DUPLICATION of the urethra occurs in association with duplication of the bladder and/or diphallus and other congenital abnormalities. Occurring as the only major deformity, duplication of the urethra has been described as complete or incomplete. In the rarer complete form there is a separate accessory urethra which has an external opening on to the skin, in addition to the normal urethra. Gross and Moore (1950) gave an account of cases reported up to 1950 together with 2 cases of their own of complete double urethra; in 1966 Casselman and Williams added 4 cases of complete duplication to the 34 then already reported in the literature. It is very unusual for the two channels to communicate with one another. The accessory external opening is usually on the penis, dorsal to the normal urethra, but may be on the glans or ventral surface of the penis and occasionally at some point removed from the penis itself. Boissonnat (1961) reported a case with the external opening at the penoscrotal junction, while Karanjavala's (1970) case had the accessory opening inside the anterior lip of the anal orifice, and in both cases the accessory urethra was more functional than the normal urethra. This is also true of the case reported by Selvaggi and Goodwin (1972) with an external opening in the perineum, and Williams (1968) refers to 3 cases with a wide channel descending from the bladder neck to open at or just outside the anus associated with a narrow and poorly functioning urethra in the normal situation.

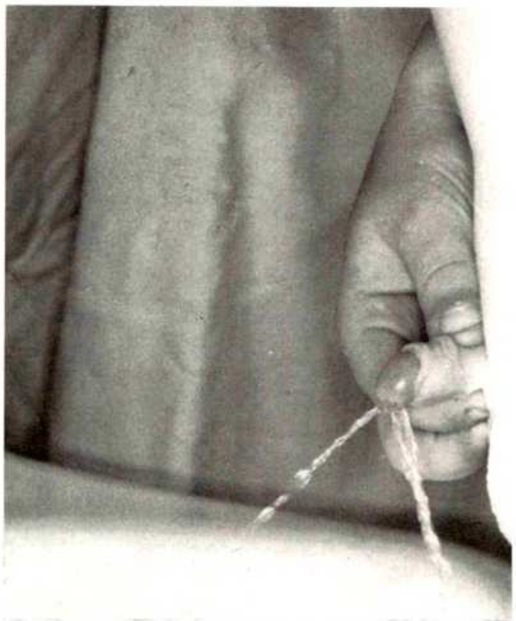

FIG. 1.—*Case* 1. The divergent streams of approximately equal power and volume.

The symptoms associated with complete duplication are listed as incontinence, infection, dorsal chordee, and double stream.

In incomplete duplication there is a segment only of the second urethra which may extend from the bladder outwards or from the penis inwards, usually to end blindly, or occasionally to communicate with the normal urethra. Infection of this accessory channel is the usual cause of symptoms.

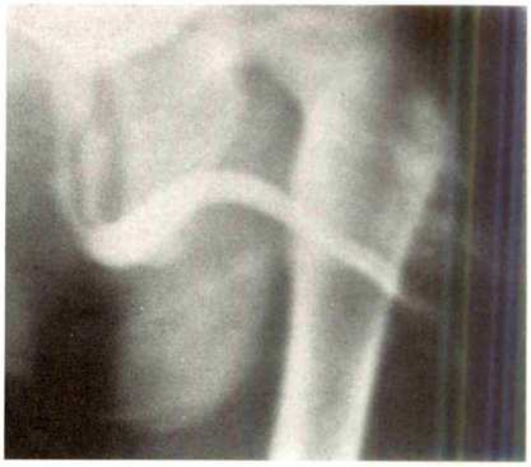

FIG. 2.—*Case* 1. Micturating cystogram which demonstrates the complete double urethra commencing just below the bladder neck.

Three cases are presented here: one of complete double urethra with two channels opening at the normally placed external meatus on the glans penis with a double stream on micturition, a second case with a complete accessory urethra opening externally on the scrotum with urinary incontinence, and one case of incomplete duplication with minimal symptoms.

CASE REPORTS

Case 1.—A. C. was first seen on 8 May, 1967, when he was 5 years old. The history was that he passed his urine in a double stream and tended to wet his legs as the two streams diverged. There was no incontinence or bed wetting. On examination he was a cheerful healthy boy who was normally developed for his age. On the glans penis in the normal situation there were two urethral orifices side by side and on micturition he was seen to pass two separate streams of nearly equal power and volume (*Fig.* 1). Probes were passed up both urethrae and there did not appear to be any connexion between the two in the penile part of the urethra.

INVESTIGATIONS.—An intravenous pyelogram showed no abnormality. A micturating cystogram demonstrated a complete double urethra, commencing just below the bladder neck (*Fig.* 2).

As this little boy had no symptoms at all, except the problem of directing his double stream so that he did not wet himself, no surgical treatment was advised at this time.

He has been followed up at regular intervals. He has managed his double stream very well and it causes him no embarrassment.

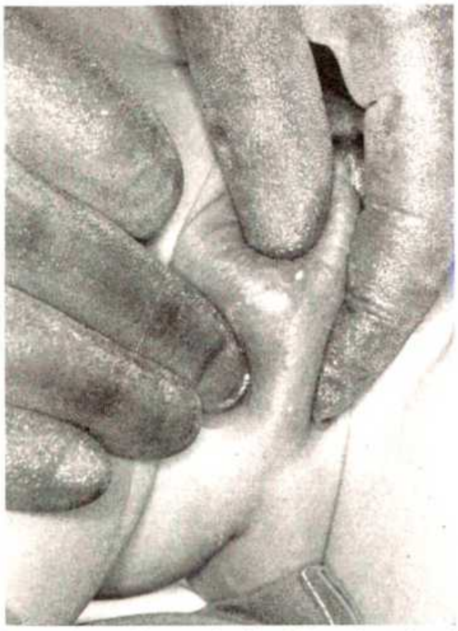

FIG. 3.—*Case* 2. Photograph of the thickened, roughened area on the right side of the scrotum; the small orifice of the abnormal urethra cannot be seen in this photograph.

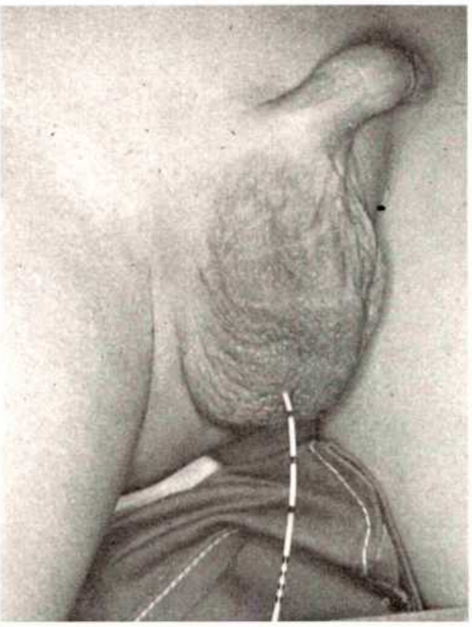

FIG. 4.—*Case* 2. A ureteric catheter inserted into the abnormal urethral orifice.

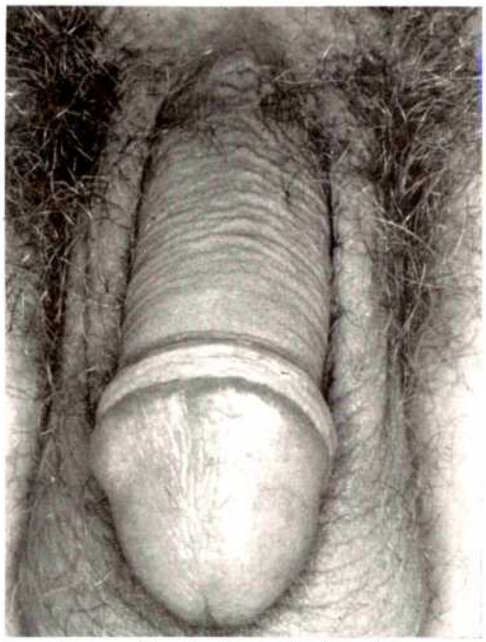

FIG. 5.—*Case* 3. The dimpling and orifice of the accessory urethra can be seen on the dorsal surface of the penis.

Case 2.—S. W., aged 3½ years, was first seen on 17 Jan., 1972. His mother said that he had always been wet since birth. About 3 weeks previously she had noticed urine draining from the right side of the scrotum. She had not observed this before. On examination he was a normally developed child. Both testes were in the scrotum. On the lower part of the right side of the scrotum a small orifice could be seen, around which the scrotal skin was thickened and roughened (*Fig.* 3). From this orifice urine could be seen to ooze out very slowly. A thickening could be felt in the scrotum on this side, separate from the testis. On compressing this thickening, fluid could be expressed from the tiny opening fairly easily. It seemed probable that this was a urinary fistula.

INVESTIGATIONS.—An intravenous pyelogram showed normally functioning kidneys and a urethrogram showed a normal urethra. No communication could be demonstrated between either the urethra or the bladder and the scrotal fistula. No abnormality of the bladder was seen on cystoscopy. A bag was fixed to the scrotum around the fistula, and urine collected in this bag continuously in a considerable quantity although most of his urine was passed via the normal urethra. A ureteric catheter was introduced into the fistula (*Fig.* 4). Injection of Hypaque into the ureteric catheter revealed a cavity in the scrotum, but no communication with the urethra or the bladder could be demonstrated.

Although radiological confirmation was not possible, a diagnosis of duplication of the urethra was made.

OPERATION (27 July, 1972).—The accessory urethra was explored and excised. A ureteric catheter was passed through the orifice and methylene blue was injected into the cavity. A very thick-walled sac was found in the scrotal tissues. It was dissected free and a narrow tube was discovered running from it up to the prostatic urethra. However, neither a ureteric catheter nor a probe could be made to enter the bladder by passing it upwards along this track. The abnormal urethra was traced up to the triangular ligament, pulled down as far as possible, ligatured, diathermied, and divided. The bladder was drained with a Foley catheter.

HISTOLOGICAL REPORT (Dr. H. J. Voss).—'Serial sections through the scrotal tissue show presence of sinus or duct lined partly by squamous epithelium, partly by transitional epithelium. Consistent with heterotopic urethra.'

Convalescence was uneventful. The patient has remained well and dry and passes urine normally.

Case 3.—D. U., aged 35 years, was seen on 5 June, 1967. He gave a history of an opening on the dorsal aspect of the penis which had been present since birth. He had never experienced any trouble with this until 3 weeks prior to being seen, when a painful lump had appeared above this orifice. The swelling had disappeared following discharge of blood from the opening. On examination there was a small orifice on the dorsal surface of the penis (*Fig.* 5) from which a little thin pus could be expressed. No other abnormality was found. Culture of the pus grew micrococci and non-haemolytic streptococci.

INVESTIGATIONS.—An intravenous pyelogram and micturating cysto-urethrogram revealed no abnormality. A urethrogram showed a normal urethra; only a trace of dye could be injected into the abnormal opening on the dorsum of the penis and this outlined a track 2½ cm. long.

In the absence of symptoms no treatment was advised or carried out at that time. A recurrence of infection with discharge of pus from the accessory urethra occurred 3 years later and responded to antibiotics.

DIAGNOSIS

A history of double stream or incontinence should alert one to the possibility of duplication of the urethra; the diagnosis of this condition seems to be long delayed in many cases, particularly with the incomplete duplications, which if they do not produce a dorsal chordee may only cause symptoms if they become infected. The finding of two urethral orifices on examination will suggest the diagnosis very strongly, and observation of a double stream or urine coming from both openings if they are not close together will confirm the diagnosis. Generally, cystoscopy and urethroscopy seem to have been unhelpful. The two urethrae can be visualized on voiding during cysto-urethrography providing that both channels convey a reasonable proportion of the voided urine, but a narrow accessory channel may not be demonstrated. Retrograde urethrograms with injection of dye into both channels may be satisfactory but again this may fail if the accessory channel is small, as in *Case* 2 reported here.

TREATMENT

In the absence of other symptoms a double stream need not be an indication for operation. If there is incontinence from the accessory urethra and a satisfactory lumen and sphincteric control of the normal channel can be demonstrated the accessory urethra should be excised. The passage of most of the urine via the accessory urethra may be a contra-indication to its excision if there is no incontinence from it. The cases described by Karanjavala (1970) and Selvaggi and Goodwin (1972) are examples of this.

AETIOLOGY

The reason for the development of a double urethra remains uncertain; the variable anatomy of the duplication cannot easily be explained by any one of the theories which have been put forward and it is likely that more than one embryological explanation is needed to account for all the cases.

Acknowledgement.—I wish to thank Mr. R. R. Popham for the photography.

REVIEWS AND NOTICES OF BOOKS

Die Behandlung der hämatogenen und der traumatischen Osteomyelitis. By Stojan Popkirov, Fruhjahr. 9½ × 6½ in. Pp. 408. Illustrated. 1971. Berlin: Veb Verlag Volk und Gesundheit. DM.172.40.

The author, Director of the Clinic for Septic Surgery in Sofia, Bulgaria, gives a detailed account of the general principles and his recommended method of treatment of 380 cases of osteomyelitis. Three-quarters of these patients suffered from haematogenous osteomyelitis, and the remainder from chronic osteomyelitis following trauma.

The radical removal of all necrotic tissue, especially bone, is stressed and the techniques for every bone are well illustrated. Over 300 of the patients received a bone-graft, with homologous grafts being transplanted twice as often as autologous grafts and three times as often as heterologous bone-grafts. In the infected non-union osteomyelitis with fractures, rigid fixation by metal implants or a 'fixateur externe' was used very rarely. Skin and muscle problems were elegantly solved by primary closure of wounds using a closed-irrigation drainage system. When several operations were included in the series 95 per cent of the patients were clinically and radiologically cured.

The book offers valuable advice for anybody who deals with the problems of osteomyelitis. The results obtained from this series of patients should be compared with other methods and experience in the future. It is also interesting to see the references from the Eastern European literature concerning bone transplantation in the presence of infection.

Textbook of Physiology and Biochemistry. Eighth edition. By George H. Bell, B.Sc., M.D., F.R.C.P., F.R.S.E., University of Dundee; J. Norman Davidson, C.B.E., M.D., D.Sc., F.R.C.P., F.R.I.C., F.R.S., University of Glasgow; and Donald Emslie-Smith, M.D., F.R.C.P., University of Dundee. 9½ × 7 in. Pp. 1160. Illustrated. 1972. Edinburgh: Churchill Livingstone. £5.

Whenever the reviewer attempts any systematic reading of texts of physiology he is impressed by the diversity of concepts, techniques, and methods which are needed in the study of human and animal function. This book is written by a physiologist, a biochemist, and a clinician; it has always had a lively and dramatic presentation and in this new edition it seems, with two-column pages and lithographic methods, more attractive than ever. This is a volume with a strong chemical bent and it contains brief but authoritative summaries of such topics as protein structure, metabolic reactions, enzyme kinetics, and chemical genetics. The presence of a clinician has ensured that the relevance to human medicine is continually emphasized. A book of this kind must have good illustrations, and these are outstanding in number and variety; the radiographs of normal chests to show the extent of variation of the cardiac shadow and the reproduction of the original print showing Forssmann's self-catheterization are particularly interesting. A number of the illustrations are in colour, and these are well reproduced.

Since physiology is primarily an experimental science, the authors have taken the trouble to include accounts of the classic experiments to enable the reader to appreciate something of the evidence on which the descriptive sections are based. In a book of this size the topics have to be condensed, but an extensive series of references and reviews for further reading is given at the end of each chapter. This is a basic text in human physiology which can be recommended to students of all ages.

Fundamental Techniques of Plastic Surgery. Fifth edition. By Ian A. McGregor, M.B., Ch.M., F.R.C.S., Glasgow. 8½ × 5½ in. Pp. 301 + x. Illustrated. 1972. Edinburgh: Churchill Livingstone. £4.

The first edition of this book was published in 1960 and the appearance of the fifth only 12 years later is testimony of its great popularity with trainee plastic surgeons and those in other surgical specialties alike; it provides basic information about which all surgeons should be aware and on which plastic surgeons can build.

There have been a number of advances in basic techniques since the fourth edition and most of these are now included in the text. Thus, the deltopectoral flap and other axial pattern flaps have almost completely replaced the tube pedicle; delayed exposed grafting is increasingly popular; sophisticated haloes have outclassed the plaster head cap in maxillofacial surgery; hand incisions other than the classic one are now widely used. Mr. McGregor's continued diligence in keeping his textbook up to date should make this edition as much sought after as its predecessors.

Transplantation. Edited by John S. Najarian, M.D., Minnesota, and Richard L. Simmons, M.D., Minnesota. 11 × 8¼ in. Pp. 797 + xiv. Illustrated. 1972. London: Henry Kimpton. £21·80.

This beautifully produced and expensive volume on transplantation is edited by clinically orientated surgeons who must, of course, have a deep interest in basic science as it affects their sub-specialty. The first part of the book is devoted to the immunobiology of transplantation—the basic science involved. The contributors to this section are able to give a most authoritative and definitive description of the processes which occur in transplanted organs and the ways in which treatment can, at least in part, circumvent them. There is always an overall clinical relevance in the book, although many of the contributions are from authors who are somewhat obliquely concerned with the care of patients.

The section on clinical transplantation covers ethical, legal, and organizational aspects as well as surgical problems. The discussion of transplantation of tissues and organs other than the kidney is somewhat more extensive than in similar volumes, and stresses the interest of the editors in transplantation as a technique in surgery rather than a specialist concern with transplantation of one organ. It seems likely that within the next decade transplantation as a surgical tool will tend to fall into place in several areas of surgery as one of a number of techniques available for the treatment of damaged or diseased tissues. For that reason the approach of the editors will continue to be a valuable one in helping the practice of surgery, in all areas, to use the best available technique for the treatment of a particular patient.

Handbuch der allgemeinen Pathologie. Volume 3, Part 6, **Lymphgefäss-System.** Edited by H. MEESEN, Dusseldorf. 9¾ × 6½ in. Pp. 708 + xiv. Illustrated. 1972. Berlin: Springer-Verlag. DM.396.

THIS volume deals in immense detail with advances in the knowledge of the lymphatic system. Each chapter is written by an authority actively engaged in research in the field, and some chapters are in English. For the research worker this is an essential reference book. The surgeon who is especially interested in this field will find much to stimulate him, and there are excellent chapters on chemistry, pharmacology, and immunology. Perhaps of greatest interest to the surgeon are the sections on pathology and the discussion on lymphangiography. The volume is unlikely to find a place in the surgeon's personal library unless he has a special interest in the lymphatic system.

Handbuch der medizinischen Radiologie. Volume 19, part 1, **Spezielle Straleuntherapie maligner Tumoren.** Edited by A. ZUPPINGER, Bern, and E. KROKOWSKI, Kassel. 10½ × 7¾ in. Pp. 824 + xix. Illustrated. 1972. Berlin: Springer-Verlag. DM.360.

THIS volume is entirely devoted to the treatment of malignant tumours and is written in German except for chapters in English on cancer of the oral cavity and cancer of the lip. Tumours of the skin and gastro-intestinal tract receive special attention, and there are comments on the use of hormonal treatment and chemotherapy.

It is a large volume with many excellent illustrations and adequate references. The text is conventional and at times somewhat didactic. It will be read with interest by the radiotherapist, and the general surgeon will benefit from consulting particular sections within his own field.

Modern Management of Myelomeningocele. By WILTON H. BUNCH, M.D., Ph.D., Virginia; ALEXANDER S. CASS, M.B., F.R.C.S., Minnesota; ALAN S. BENSMAN, M.D., Minnesota; and DONLIN M. LONG, M.D., Ph.D., Minnesota. 9 × 6 in. Pp. 251 + ix. Illustrated. 1972. St. Louis: Warren H. Green Inc. $15.00.

THIS brief book claims to be written for all who see and treat myelomeningocele, its avowed aim being to bring together the various medical specialists concerned with this condition, but also to be written for both medical and paramedical personnel. The four authors are a neurosurgeon, an orthopaedic surgeon, a urologist, and a rehabilitation expert; in addition, there is a chapter on intellectual and emotional development by two psychologists. There are reasonable references to the literature but the book in fact reports the methods and views of a single group of enthusiasts. Inevitably the orthopaedic and urological chapters reflect the approach of the respective authors, because views differ widely in these areas; these two chapters contain many pages of radiographs. Probably the best chapter, because it would be of use to a wide range of readers, is that on 'Habilitation of the Child with Myelomeningocele'. Incidentally the book also makes reference to the treatment of spina bifida occulta in patients with only dimples on the spine which really presents quite different problems to myelomeningocele.

Although the authors make reference to the view that treatment may sometimes be unwise or unjustified, it is clear that they themselves are committed to treating virtually all children. The term 'aggressive team approach' occurs five times in two pages and this indicates a degree of optimism which was common five or ten years ago in Britain but which is currently giving way to a more realistic and sober assessment of the therapeutic possibilities.

General Thoracic Surgery. Edited by THOMAS W. SHIELDS, M.D., Chicago. 10 × 7 in. Pp. 1007 + xxi. Illustrated. 1972. London: Henry Kimpton. £20·25.

THE publication of this book is timely; because of the striking advances made in cardiac surgery there is a danger that surgical training programmes may overlook the great volume of general thoracic surgery that has to be done throughout the world. Dr. Shields has mustered a fine team to add much to his own considerable contribution in this comprehensive book. In a graceful foreword Dr. Paul Sampson writes: 'Dr. Shields has picked his 56 contributors for their specialised knowledge, their professional reputation and their ability to write.' Multiple authorship often leads to patchiness, but this cannot be said of this work.

The division of the book into 14 sections, subdivided into 43 chapters, laid out in a clear style encourages the reader from the moment that he opens the book; the 3 Contents pages are elegantly designed and printed. The basic science contributions in Sections 1 and 2 are clear, up to date, and fit in well with accounts of the supporting disciplines, which are essential for good thoracic surgery, including anaesthesia, radiology, bacteriology, mycology, and parasitology.

The section on operative procedures contains much information of value to senior residents and practitioners of general surgery who may find themselves involved, because of local conditions of time and place. Perhaps the omission of oesophageal surgery may be regretted by many 'general' thoracic surgeons. There is a good account of diaphragmatic and hiatal hernia practice.

In a book written by so many experts it is difficult and unnecessary to single out particular chapters; the reviewer found much of interest in the accounts of tracheal surgery, the correction of sternal deformities, and the section on the mediastinum.

'Pulmonary' conditions are thoroughly covered by a large section containing much valuable information in the 290 pages devoted to the subject. The present practice of surgery for cancer is excellently stated. The less common lung diseases, which from time to time deceive the most experienced thoracic surgeons, such as anomalies, hydatid cyst disease, and other 'rarities', are clearly outlined. The chapter on the present state of lung-transplantation research is short but authoritative.

It was a pleasure to read this outstanding contribution which should find its way to the shelves of every medical library.

Urologische Operationslehre. Volumes 9 and 10. Edited by G. W. HEISE, Magdeburg, and E. HIENZSCH, Jena. 10½ × 7¼ in. Vol. 9, pp. 180; Vol. 10, pp. 172. Illustrated. 1972. Leipzig: Veb Georg Thieme. Vol. 9, 58M.; Vol. 10, 53M.

TWO further volumes of this multi-author work on operative urology have now appeared. Volume 9 deals first of all with those procedures which come somewhere between gynaecology and urology, and there is an extensive section on the management of vesicovaginal and other types of lower urinary fistulae. The question of incontinence is also dealt with, and as the author of this section is a gynaecologist the preference for vaginal procedures is not surprising. The many different types of operative procedure are described in detail and are extremely well illustrated by clear line diagrams. The second section of this volume deals with intersexuality and the various problems of pseudohermaphroditism. The differential diagnosis is clearly pointed out and the operative management is again well illustrated by diagrams. Both sections of this book have an extensive bibliography.

Volume 10 deals with operations on the kidney and has an excellent section on the various methods of surgical exposure of the kidney. This section is also extremely well illustrated. There follows a chapter on the surgical technique of the removal of parathyroid tumours which is probably outside the scope of the average British urologist. The final two chapters in this volume deal with the medical treatment of urinary calculi in general and the conservative treatment of cystine stones.

Both volumes should be of interest to urologists, especially because of their extremely clear diagrammatic illustrations of operative procedures. These publications also show that the present trend of thinking in the German Democratic Republic is very similar to that in other European countries.

Clinical Neurosurgery, Volume 19. Edited by GEORGE T. TINDALL, M.D., Galveston. 9 × 6 in. Pp. 598 + xlvi. Illustrated. 1972. Edinburgh: Churchill Livinsgtone. £12.

THIS rather expensive volume contains the edited proceedings of the Twenty-first Annual Meeting of the (American) Congress of Neurological Surgeons held in Miami in 1971. The congress was devoted to the topic of head trauma and the book is dedicated to the congress's honoured guest, Dr. E. S. Gurdjian. The volume also contains a cumulative index of the 19 volumes of *Clinical Neurosurgery* so far published.

The chapters, in the form of edited papers given at the Miami meeting by 36 distinguished contributors (mostly from the United States but Canada, Australia, and the United Kingdom are also represented), cover a wide variety of clinical and scientific subjects concerned with head injury. Mostly they deal with problems of prevention and management which are currently uppermost in the thoughts of those concerned with the care of cerebral trauma.

The chapters deal with the experimental mechanisms of head injury, patient monitoring, circulatory changes, lung function, diagnostic procedures, medical management, metabolic disturbances, prevention and mechanisms of road and sports accidents, cerebrospinal fluid 'leaks', vascular trauma, and many other subjects. There is a particularly valuable chapter by Professor Jennett indicating how better and earlier prognosis of the severe cerebral injury may be achieved.

Each chapter is a study in some depth and represents the clinical or research interests of the contributor. As a survey of current thought this is an excellent volume for reference and contains good subject bibliographies, but like all conference compendia of this nature it is expensive and its value is likely to be ephemeral. A less expensive format might have enabled earlier publication and wider dissemination. Nevertheless, for the libraries which can afford it the book is a very worth-while purchase and the cumulative index is especially valuable.

Diagnostic Orthopaedic Pathology, By C. G. WOODS, B.Sc., M.B., Ch.B., M.R.C. Path., Consultant Pathologist, The Nuffield Orthopaedic Centre, Oxford. 9½ × 7½ in. Pp. 297. Illustrated. 1972. Oxford: Blackwell Scientific Publications. £8·50.

THIS book is a lucid presentation of much of the field of orthopaedic pathology. It begins with technical considerations and then outlines the normal and articular tissues, the latter in detail. The subsequent chapters deal with congenital and acquired abnormalities of growth, and there are further chapters on acquired bone disease, including tumours. Emphasis is placed on the need to use all the information available in order to reach a valid conclusion in cases where there are similarities in the histological appearances of different bone lesions.

In each chapter the text precedes the illustrations, which are well chosen, clear, and well described. The book contains few references and is more the personal expression of the author's viewpoint, which is sound, realistic, and practical. This is a book for anyone who wants to learn about orthopaedic pathology.

Supportive Care of the Surgical Patient. By WILLIAM M. STAHL, M.D., New York. 9 × 6 in. Pp. 270 + xvii. 1972. New York: Grune & Stratton, Inc. $13.50.

THIS book will fulfil an important role in furnishing both undergraduate students and those destined for examinations such as the primary F.R.C.S. with factual knowledge about facets of patient management which are so often acquired haphazardly. Because the book is clearly based on physiology it will have particular appeal to students grappling with what are considered by clinicians to be the basic sciences. In a sense it is applied physiology, covering cardiorespiratory, renal, metabolic, and endocrine functions with a glance at the skin, the emotions, and the autonomic nervous system. The author presents them in terms of survival systems for which he creates an original nosological classification—exchange systems (e.g. O_2 exchange), transport systems, and regulatory systems. It is a useful book with an adequate bibliography, although it is expensive for a work without illustrations.

Recent Advances in Gastroenterology. Edited by JOHN BADENOCH, D.M., F.R.C.P., United Oxford Hospitals, and BRYAN N. BROOKE, M.D., M.Chir., F.R.C.S., St. George's Hospital Medical School, London. 9¼ × 6¼ in. Pp. 350 + ix. Illustrated. 1972. Edinburgh: Churchill Livingstone. £6.

THIS book is not only for gastro-enterologists but for all who are involved with the treatment of abdominal disease. Each chapter is written by an authority and the text is lucid and well illustrated. The contents range widely through some of the topics of current interest in gastroenterology, dealing with basic science in some chapters and with treatment in others. There are liberal references and the cost for such a volume is very reasonable.

The need for authoritative review articles is ever increasing. The succinct appraisal of new methods and ideas demands a technique of writing which requires judgement and experience if it is to educate and not confuse the reader. The editors are to be congratulated in achieving precisely this object.

Symposium on Myelomeningocele. AMERICAN ACADEMY OF ORTHOPAEDIC SURGEONS. 9¾ × 7¾ in. Pp. 317 + xiii. Illustrated. 1972. London: Henry Kimpton. £10·80.

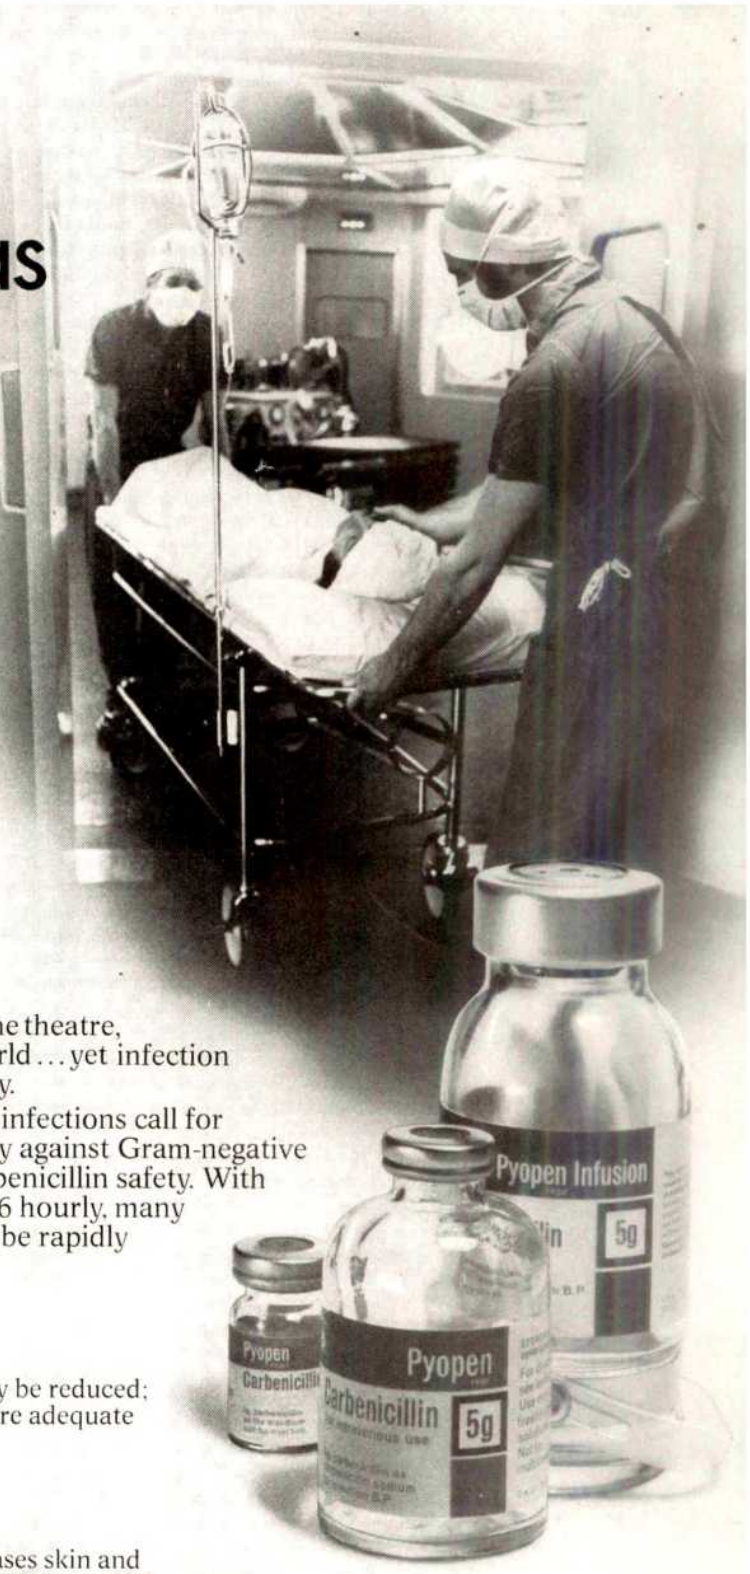
THERE are surgeons in the fields of genito-urinary, orthopaedic, paediatric, and even neurological surgery who have yet to encounter the challenge presented by the child with myelomeningocele. For them and for those who already struggle with the problem this book would provide much enlightenment.

The 31 chapters are drawn from the papers and discussions at a course on myelomeningocele in 1970 under the aegis of the American Academy of Orthopaedic Surgeons. Most of the authors are from North America, but the Sheffield group in Britain, a *pioneering team* in the management of children with myelomeningocele, is worthily represented.

The book, which is well printed, has illustrations of an exceptionally uniform excellence. The first few chapters deal with embryology, pathology, and the evaluation of the potential ability of the newborn baby with myelomeningocele, followed by sections on hydrocephalus and genito-urinary and bowel disorders. Orthopaedic and developmental problems are next discussed; the psychosocial aspects are considered and long-term follow-up data are presented. Finally, there are two chapters on the team approach to the care of these unfortunate children.

Many of the subjects are controversial and are a source of disagreement among surgeons of experience. Due regard for other views is shown by most contributors to the book and their clear presentation of personal data and opinions will be of interest and value to a wide variety of readers.

When pseudomonas threatens the success of surgery



Pyopen

The skill of the surgical team, hours in the theatre, the most advanced techniques in the world . . . yet infection can still throw the outcome into jeopardy.

Post-operative pseudomonas or proteus infections call for Pyopen. Only Pyopen offers good activity against Gram-negative organisms with the added advantage of penicillin safety. With intravenous Pyopen, at a dosage of 5g 4-6 hourly, many dangerous post-operative infections can be rapidly controlled.

Adult Dosage
5g I.V. 4-6 hourly.
In patients with renal impairment dosage may be reduced; monitoring is advisable in these cases to ensure adequate serum antibiotic levels.

Contra-indication
Penicillin hypersensitivity.

Side-effects
As with other injectable penicillins. In rare cases skin and mucous membrane haemorrhages due to interference with normal clotting mechanisms have been reported.

Pyopen–by infusion or injection

Further information is available on request.
Pyopen* (carbenicillin sodium B.P.) is a British product originated by
Beecham Research Laboratories, Brentford, England.

Isolated Organ Perfusion

This book provides the general background of scientific and technical knowledge which a research worker will need to embark on a project involving perfusion on a viscus. Basic principles necessary to achieve good preparations have been derived from over 1500 organ perfusion studies in order to make the authors' experience in this fascinating field available to others.

H. D. Ritchie is Professor of Surgery at London Hospital Medical College and J. D. Hardcastle is Professor of Surgery at the University of Nottingham.

Mammography, Thermography and Ultrasonography in Breast Disease

Kenneth T. Evans MB, ChB, DMRD, FRCP, FFR, and
I. Huw Gravelle BSc, MB, ChB, DMRD, FRCP, FFR

Increasingly sophisticated methods have been developed in recent years for the investigation of patients with breast disease. In this monograph the authors have described and evaluated mammography, thermography and ultrasound, and the principles on which each is based. The superiority of mammography is clearly shown, and the complementary roles of thermography and ultrasonography to mammography are also demonstrated. The book includes a splendid collection of illustrations which provide a concise and yet comprehensive guide to imaging techniques in breast disease. It is a part of the *Radiology in Clinical Diagnosis Series* edited by David H. Trapnell.

Postgraduate Surgery Lectures—1

Edited by John McFarland MD, ChM, FRCS

Each of the seven chapters of this book is an adaptation of a lecture delivered at the 1971–72 season of postgraduate lectures given at the Liverpool Medical Institution. These papers have been adapted for publication by some of the distinguished speakers at that occasion; each gives an account of the subject on which he is an international authority. The book therefore reflects the most recent advances in surgery and will be of immediate practical interest to all postgraduate surgeons and physicians.

Important New Editions

EYE SURGERY. 5th Edition

H. B. Stallard, M.B.E., T.D., M.A., M.D. (CANTAB.), M.CHIR., F.R.C.S. (ENG.), HON.LL.D. (ST. ANDREWS), *Surgeon, Moorfields Eye Hospital; Eye Surgeon, St. Bartholomew's Hospital.*

This new and completely re-designed edition covers the whole field of eye surgery including orbital and reconstructive (plastic) surgery. Complete updating of material with an individual selective approach to operative procedures rather than a general survey of the possible techniques makes this the authoritative work for all eye surgeons. Postgraduates will find it fully covers their needs. As a reference book it should be in every library.

946 pages 779 illustrations **£13·25**

A MANUAL OF ANAESTHETIC TECHNIQUES. 4th Edition

W. J. Pryor, M.B., CH.B. (N.Z.), F.F.A. R.C.S. (ENG.), D.A. (ENG.), F.F.A. R.A.C.S., *Anaesthetist, Christchurch Hospital, New Zealand,* and D. C. T. Bush, V.R.C., M.B., CH.B. (N.Z.), D.A. (ENG.), F.F.A. R.A.C.S., *Anaesthetist, Christchurch Hospital, New Zealand.*

Amongst the new sections added to this completely revised edition are neurolept-analgesia and dissociative anaesthesia. This should be of great interest to house surgeons, anaesthetic registrars, and those in need of specialized information.

424 pages 123 illustrations **approx. £7·00**

Important New Book

COMMON SURGICAL EMERGENCIES

C. B. Williams, M.D., F.R.C.S., *Senior Registrar in General Surgery, United Bristol Hospitals.*

This book is designed to provide the information needed for the 'on the spot' management of surgical emergencies. It also includes a list of drugs in common use under these conditions.

156 pages Illustrated **£1·50**

JOHN WRIGHT & SONS LTD., BRISTOL, ENGLAND BS8 1EX

RADIOTOM 619

for surgical diathermy

The *RADIOTOM 619 is a universal electrosurgical apparatus designed to meet all the clinical requirements of general surgery and the special requirements of neurosurgery.

The RADIOTOM 619 can be placed on a trolley. The small dimensions and the low weight of the unit also make it possible to mount it in a ceiling column, build it into a wall or to use it on a wall bracket or a floor column.

TRAUMA SURGERY: EXCEPTING BONES AND JOINTS

P. Powley, M.B., B.S., F.R.C.S., *Consultant Surgeon, Swindon and District Hospital Group.*

This book is designed for hospital staff involved with the reception and initial treatment of the victims of accidents—either road or industrial. It explains in detail the various injuries to the parts of the body other than the main bones and stresses which injuries require specialist treatment from the onset.

136 pages 14 illustrations Paper Covers **£1·50**

Other Important Surgical Titles

HAMILTON BAILEY'S EMERGENCY SURGERY. 9th ed.

Edited by T. J. McNair, M.D., F.R.C.S. (EDIN.), F.R.C.S. (ENG.)

CHURCHILL LIVINGSTONE

THE UNFAVORABLE RESULT IN PLASTIC SURGERY: Avoidance and Treatment

Edited by ROBERT M. GOLDWYN, MD, Assistant

1973 640 pages 279 illustrations **£17·50**

By its focus on unfavorable results, this text differs from most in plastic and reconstructive surgery because it is devoted solely to the unpleasant realities of our speciality. It contains information that we would like to obtain at meetings and in articles but seldom do.

Although medicine has evolved to the point where it acknowledges mistakes, a certain amount of hush-hush, nevertheless, remains. Formerly, pride and ignorance were the cause of this reticence; now fear of litigation is also a factor. In many ways, this book makes plastic surgeons less vulnerable to adverse legal proceedings, not only because its information should upgrade our skills, but also because it confronts and confirms our fallibility.—*Extract from the preface.*

A SHORT TEXTBOOK OF SURGERY

SIR CHARLES ILLINGWORTH

1973 Ninth Edition 320 pages
250 illustrations **£5·00**

This is not so much a new edition as a metamorphosis. In the 34 years since this textbook first saw the light there have been amazing advances in nearly every field of surgery, and repetitive attempts to keep the book up to date inevitably had led to some unevenness in presentation. A total reappraisal seemed essential.

It remains a 'Short Textbook' in name, and in the number of words and pages, but we believe that it is as comprehensive in scope as many larger compilations. Its brevity has been achieved by concise use of English prose and by eliminating many of the needless minutiae and petty irrelevances with which textbooks tend to become incrusted.—*Extract from the preface.*

CURRENT PRACTICE OF BILIARY SURGERY

GABRIEL A. KUNE

1972 442 pages 164 illustrations **£8·00**

This book is based on a clinical approach, emphasising safety and effectiveness in surgical technique. Dr. Kune explains the surgical anatomy and physiologic function of the biliary tract as well as pathologic changes that occur with disease. Subtle variations in the anatomic relationships of blood vessels and bile ducts in the biliary system are given careful attention. He also presents his original contributions on proximal bile duct anatomy, accessory and aberrant bile ducts, and the surgical anatomy of the distal common bile duct.

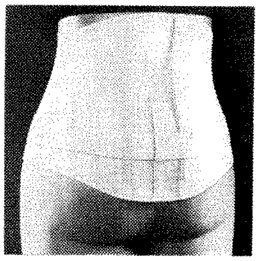
Standard Fabric Spinal Supports by Remploy

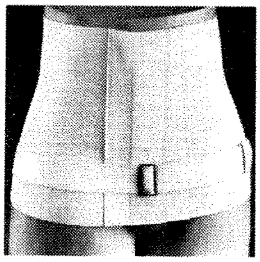
Although it isn't yet fully understood why lower lumber supports relieve pain, there's little doubt that they do.

Because the choice of support depends on many things – the complaint, its severity, and even the patient's job – we now offer a comprehensive range of standard supports. They're all designed to give immediate relief following diagnosis and a stock held in your Department will not only allow for immediate treatment, but also reduce the number of outpatient visits and speed the patient's return to work.

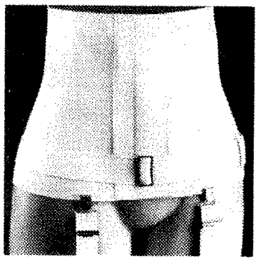
So write for a catalogue that gives full details of spinal supports and our range of rehabilitation equipment.



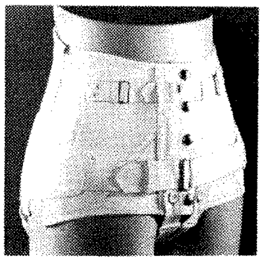
Rembelt Code OA 24
Spinal support in drab or white coutille, reinforced with two metal strips, fastened in front with velcro fastening, 8″ elastic inserts, fulcrum strap with buckle. Five sizes covering waist measurements: 25″-28″, 29″-32″, 33″-36″, 37″-40″, 41″-44″. Depth at back 10″, depth at front 8″. Suspenders or understraps as required.



Rembelt Code OA 24/1
As above but with back depth 13″, and front depth 10″. White coutille only.



Rembelt Code OA 24/2
As OA 24/1, but with wider hip measurements to accommodate the fuller female figure. White coutille only. Clip on suspenders.



Rembrist Belt Code OA 24/3
Standard lumbar sacral support in white coutille. Made in a range of three waist sizes: 28″-33″, 34″-38″, 39″-44″. Adjustment by means of side lacing. Press stud fastening for men. Velcro fastening for ladies. Wide fulcrum strap with buckle. Available depths 11″ back and 8″ front for men, 13″ back and 9″ front for ladies.

. . . but what happens in the patient's legs?

"The venous return seems to be carried through a few transport vessels during operation, while the majority of the veins of the calf appear to be excluded from participation in venous return. This exclusion from venous flow in the legs was considered to be a main factor in the establishment of postoperative thrombosis.

Infusion of 500 ml 10% dextran 40* during general anaesthesia and abdominal surgery maintained or restored preoperative flow pattern in the venous system of the lower extremities.

The thrombosis protecting effect of dextran found in this study together with the effect of dextran 40 on venous flow reemphasizes the importance of flow improvement for the prophylaxis of postoperative thromboembolism."

A

SEPTRIN TACTICS

first

SEPTRIN ensures coverage against all likely bacterial pathogens.

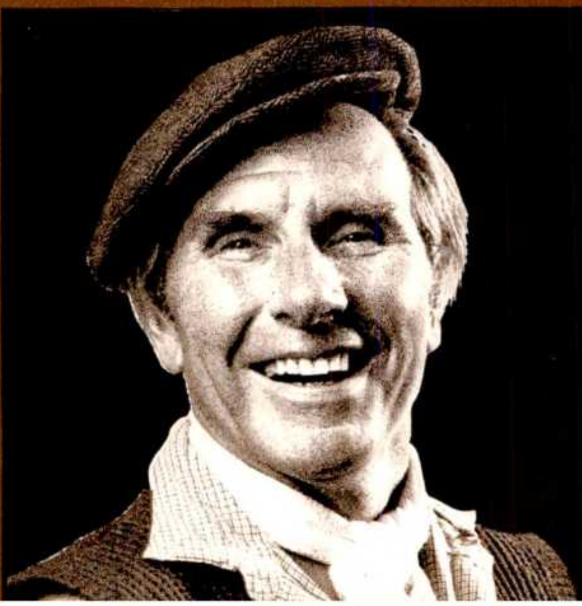
fast

SEPTRIN rapidly obtains effective blood levels with simple twice daily dosage.

decisive

SEPTRIN crushes bacterial resistance with a bactericidal action which differs essentially from that of other antibacterials.

they've proved superior in bronchitis



Superior to either ampicillin or tetracycline as judged by reduction in sputum purulence or sputum volume.[1,2]

"...not only are the two primary pathogens, *Strep pneumoniae* and *H influenzae*, sensitive, but so are the secondary invaders such as klebsiella which often replace them after antibiotic treatment."[3]

"...can only be considered excellent on the criteria originally specified, namely the elimination of the infecting micro-organism."[4]

INSTRUCTIONS TO AUTHORS

Preparation of MS.—Papers should be submitted in typescript and the author should retain a carbon copy. Double spacing should be used throughout, except for quotations.

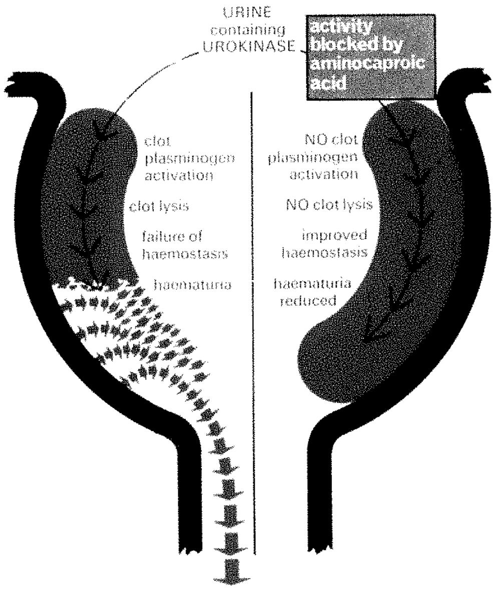
Tables and Illustrations.—Tables should be numbered in roman numerals and set out on sheets separate from the text. Illustrations, too, should be kept separate from the text and should be numbered consecutively in arabic numerals. Each figure should be referred to in the text, and the descriptive legends should be typewritten on a separate sheet of paper, and not put on the backs of the originals. Glossy photographs should be supplied unmounted and positive prints (not X-ray films or lantern slides), also unmounted, should be sent whenever possible. Drawings should be in a finished state suitable for reproduction. When *coloured illustrations* are submitted as colour prints they should be accompanied by the actual transparencies where possible. As coloured illustrations are very expensive to reproduce, the author may on occasion be asked to make a contribution towards the cost.

References.—The arrangement is based on the Harvard System.

In this system the name of the author and the date of the publications are given in the text; the list of authors quoted is put at the end of the article in alphabetical order. Each reference in the list should give, in order, the author's name, initials, the year of publication (in brackets), the name of the journal, the volume (in heavy type arabic numerals), and the number of the first page of the paper. If the author cited has written more than one paper in the year, each should be distinguished by the letters a, b, and c, etc. For books, the place of publication should be stated and the publisher's name. The names of collaborating authors should be given in full on the first occasion, but in later citations the words "and others" should follow the first name. Abbreviations for journals should be those adopted in the "World List of Scientific Periodicals" (1963).

Only in papers in which many and frequent references have to be made should the items be numbered; the numbers may then be inserted in the text without interrupting it with a list of names.

The mechanism of post-prostatectomy bleeding and EPSIKAPRON® control



URINE containing UROKINASE
activity blocked by aminocaproic acid
clot plasminogen activation
clot lysis
failure of haemostasis
haematuria
NO clot plasminogen activation
NO clot lysis
improved haemostasis
haematuria reduced

Epsikapron (aminocaproic acid) is rapidly excreted in the urine in high concentration ; there it inhibits urokinase, the fibrinolytic enzyme in urine. With the haemorrhage-sustaining property of urine blocked, the haemostatic coagulum becomes adequate, and blood loss is diminished substantially.

Epsikapron makes your prostatectomy patient's post-operative course smoother by diminishing :

the need for post-operative blood transfusion
clot retention
catheterization
the risk of infection
the period of hospitalization

Presentation

Epsikapron Solution for Injection 0.4 g/ml Box of 6 ampoules of 10 ml, each containing 4.0g aminocaproic acid (0022/5003) Epsikapron Effervescent Powder 50% Box of 30 sachets, each containing 3.0g aminocaproic acid (0022/5004) Epsikapron Syrup 0.3g/ml Bottle of 250ml (0022/5005)

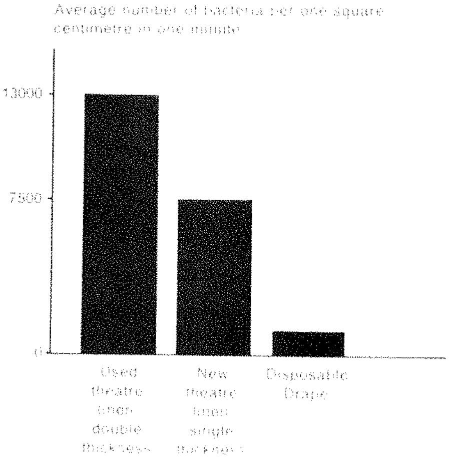
The quiet Revolution

1973-72-71

The change began over two years ago, as the result of an extensive programme to develop a system superior to traditional balloon cloth drapes.

The primary requirement was that the drape fabric should resist "strike-through" of moisture and thus bacteria–a risk associated with the use of balloon cloth over 20 years ago[1]



BACTERIAL PENETRATION OF SURGICAL DRAPING

Average number of bacteria per one square centimetre in one minute

BARRIER* fabric was created–tough but soft–and combined with absorbent, impermeable and adhesive areas to give specifically designed drapes for *all* areas of surgery.

1. Editorial *The American Journal of Surgery*, February 1952, Wm. C. Beck, M.D., Thomas S. Collette, B.A.
2. Penetration of Surgical Draping by Bacteria, Peter Dineen, M.D., Hospitals, *Journal of the American Hospital Association*, Vol. 43. Oct. 1st, 1969.

The BARRIER* Drape system was thoroughly evaluated and then adopted –slowly but surely–by hospitals numbering over 250 to date throughout the U.K.

Convenient, reliable and, of course, different–the BARRIER* Drape system has been recognised by the smallest to the largest organisation in the Health Service, who have called on BARRIER* Drapes to supply the needs of over 150,000 procedures, and growing!
The BARRIER* Theatre Drape System represents the progressive thinking of surgical teams and hospital administrators towards the new opportunities available for theatre planning.
***They* have made the change.**

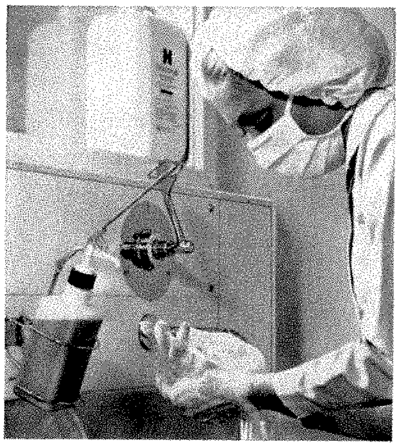
Now ICI bring to surgical scrubs the proven advantages of Hibitane in

hibiscrub

TRADE MARK



Antibacterial Activity

From the bacteriological point of view the demand is for a surgical scrub which combines maximum antibacterial activity with pronounced residual effect.

'Hibiscrub' fulfills these requirements. It is not only rapidly effective against both gram positive and gram negative organisms but also exhibits good residual activity – a major advance in the development of surgical scrubs.

Hand Care

The effect of prolonged usage on the hands of surgical staff is a critical factor in the acceptability of any surgical scrub. Sensitivity reactions, excessive detergency etc., can lead to the abandonment of certain scrub regimes.

'Hibiscrub' is positively pleasant to use – nurses using it regularly have reported on the excellent condition of their hands.

VAGOTOMY ON TRIAL

Edited by A. G. COX, MD, FRCS, and J. ALEXANDER-WILLIAMS, MD, ChM, FRCS

The treatment of severe peptic ulcer remains the surgeon's responsibility and vagotomy in its different varieties is now the principal weapon in the surgical armamentarium. This book is the latest in depth enquiry into the claims made for vagotomy.
Emphasis is laid throughout on objective evidence from controlled clinical trials and this combined with comprehensive coverage of the subject will commend the book to all students and practitioners of gastroenterology.

When pseudomonas threatens the success of surgery

Pyopen

The skill of the surgical team, hours in the theatre, the most advanced techniques in the world ... yet infection can still throw the outcome into jeopardy.

Post-operative pseudomonas or proteus infections call for Pyopen. Only Pyopen offers good activity against Gram-negative organisms with the added advantage of penicillin safety. With intravenous Pyopen, at a dosage of 5g 4-6 hourly, many dangerous post-operative infections can be rapidly controlled.

Adult Dosage
5g I.V. 4-6 hourly.
In patients with renal impairment dosage may be reduced; monitoring is advisable in these cases to ensure adequate serum antibiotic levels.

Contra-indication
Penicillin hypersensitivity.

Side-effects
As with other injectable penicillins. In rare cases skin and mucous membrane haemorrhages due to interference with normal clotting mechanisms have been reported.

Pyopen-by infusion or injection

The collaborators.

We have our own workshops where skilled craftsmen make Seward surgical instruments. Nothing less than ultimate perfection will satisfy them.

Our sales people's viewpoint is also important. They're in constant touch with the medical profession. So they know what is wanted – and why.

Then there's the surgeon. We never hesitate to ask a surgeon for his advice. After all, we make surgical instruments, and he uses them. So it's naturally beneficial to work closely together, for both of us.

It's true we have an enviable reputation at Seward for fast delivery of our instruments.

But when it comes to design, we take all the time it needs to get things right.

ASSOCIATION OF SURGEONS OF GREAT BRITAIN AND IRELAND

The annual meeting of the Association took place in Aberdeen on 4, 5, and 6 April, 1973, with the President, Mr. W. Michie, M.B.E., in the Chair.

The major symposium was entitled 'Modern Trends in the Management of Thyrotoxicosis'. These papers, and others in the subsequent sections of Short Papers and Short Papers for the Moynihan Prize, follow in the order in which they were read. A report of the symposium on General Surgical Training has been contributed by Mr. M. R. Williams (Canterbury).

SYMPOSIUM ON MODERN TRENDS IN THE MANAGEMENT OF THYROTOXICOSIS

OPENING ADDRESS

BY W. MICHIE
ABERDEEN ROYAL INFIRMARY

THYROTOXICOSIS is a relatively common disorder with a recorded annual rate of 30 per 100,000 of female population and 20 per 100,000 for both sexes (Furszyfer, Kurland, McConahey, and Elveback, 1970). Despite its frequent occurrence its aetiology remains obscure, its management debatable, and its aftercare problematical. Current thinking involves aetiological factors outwith the hypothalamic–pituitary–thyroid axis, and implicates auto-immune reactivity, either directly from the deposition of immunoglobulins in the basement membrane of the thyroid follicle (Werner, Wegelius, Fierer, and Hsu, 1972) or indirectly by delayed hypersensitivity from defective lymphocytic immune surveillance (Volpé, Edmonds, Lamki, Clarke, and Row, 1972). Yet again the manifestations of Graves' disease have been ascribed to defective thyroid autoregulation of iodine excess and depletion and consequent loss of ability to modulate thyroid function and activity (Ingbar, 1972).

Were the aetiological factors of Graves' disease elicited and understood, it is possible that treatment would be on a defined and rational basis. A generally acceptable treatment has yet to be evolved, and the plurality of therapies currently in vogue merely confirms the aphorism first expressed in 1905 by Dr. Hector Mackenzie, a physician of St. Thomas's Hospital, that when for a particular disease there are many remedies, none will be very efficacious. At present the thyrotoxic patient is treated by destructive therapy by radio-isotopes or surgery, or by long-term surveillance on anti-thyroid drug therapy in the hope of eventual spontaneous remission. Each method has its advantages, disadvantages, and complications. The commonest complication of both methods of destructive therapy is hypothyroidism, though the time interval and incidence differ considerably in each. Provided that an adequate remnant is left, the hypothyroid rate 1 year after operation is in the region of 30 per cent, and if the index of clinical suspicion during this year is sufficiently high, hypothyroidism will rarely develop later than 1 year after operation (Michie, Pegg, and Bewsher, 1972). In contrast, the hypothyroid rate after radio-iodine therapy has been recorded as high as 41 per cent at 1 year, with an annual increase thereafter of

2·8 per cent (Nofal, Beierwaltes, and Patno, 1966). Radio-isotopes are presumed to act by interference with the replicative mechanism of the thyroid follicular cell (Greig, 1965), and the implication is that the eventual end-point of radio-iodine therapy is hypothyroidism in all patients.

While a reasonable prediction of the incidence of hypothyroidism can be made for a group of patients treated by either radio-iodine or surgery, the fate of the individual patient cannot be predicted with any accuracy. It is for this reason that a renewed attempt is being made to assess the value of long-term antithyroid drug therapy supplemented by the evidence of serial 20-minute uptake of radio-iodine or pertechnetate (Alexander, McLarty, Horton, and Pharmakiotis, 1973). While it is unlikely that antithyroid drugs affect the fundamental nature of the disease, they inhibit hormone production until a natural remission, estimated variously as occurring in between 30 and 50 per cent of patients, becomes apparent. The programme which this form of therapy imposes on the patient, with the demands on trained personnel for continuing supervision and the uncertain nature of the outcome, are factors which might tend to limit its general acceptance.

Irrespective of whether control of thyrotoxicosis is actively pursued by destructive therapy or passively awaited from the long-term use of anti-thyroid drugs, there devolves upon the clinician an ethical responsibility for continuing supervision and follow-up of his patient, and this responsibility cannot be lightly undertaken. Overt hypothyroidism can be readily confirmed by routine tests of thyroid function, but forms less clinically obvious exist whose detection rests on elevation of serum thyroid-stimulating hormone levels (Hedley, Hall, Amos, Michie, and Crooks, 1971). This is of some importance for the younger patient with mild persisting hypothyroidism who may be at long-term risk of developing ischaemic heart disease (Bastenie, Vanhaelst, Bonnyns, Neve, and Staquet, 1971).

The number of patients each year may remain relatively constant, but the total number of patients at risk of iatrogenic hypothyroidism accumulates and becomes part of an increasing clinical burden. This burden has in some measure been solved for selected populations in Scotland by an annual follow-up programme controlled by a computer-based register, which has been formulated as a joint venture between general practitioner and hospital consultant (Hedley, Scott, Weir, and Crooks, 1970).

One further aspect of the management of the thyrotoxic patient merits investigation. The cost of treatment to the health service and the economic burden of frequent attendance at hospital for the patient, taken in conjunction with overburdened facilities and an inadequate number of trained personnel, are factors which cannot any longer be ignored. A study of comparative costs of different forms of treatment might prove rewarding. Such a study is now overdue.

RADIOACTIVE IODINE THERAPY FOR THYROTOXICOSIS

By WILLIAM R. GREIG

UNIVERSITY DEPARTMENT OF MEDICINE AND NUCLEAR MEDICINE, ROYAL INFIRMARY, GLASGOW

SUMMARY

Radioactive iodine has been used to treat over 300,000 thyrotoxic patients since 1946. This paper reviews the knowledge gained in the past 23 years about the efficacy and safety of ^{131}I therapy for thyrotoxicosis. Modifications with reference to case selection, dosage, and follow-up are discussed.

RADIOACTIVE iodine (^{131}I; half-life 8 days) in therapeutic amounts destroys thyrotoxic follicular cells and damages the stroma of the gland; there is very little radiation given to, and very rarely any damage incurred by, tissues adjacent to the thyroid, and the same applies to the adult body as a whole.

More than 20 years' experience of the use of ^{131}I in the treatment of thyrotoxicosis has shown that it is safe and effective and is undoubtedly the treatment of choice in all elderly patients and especially in those who are frail and have complications. ^{131}I therapy is also advised for adult patients with a postoperative recurrence of thyrotoxicosis and for those in whom drug therapy has failed for some good reason and in whom operation is refused or contra-indicated.

Children and adults of less than 25 years of age should be considered for ^{131}I therapy only in exceptional circumstances, and it is absolutely contraindicated if the patient is pregnant or likely to be. If the patient is fertile, contraception is advised for up to 1 year after successful therapy.

The size and characteristics of the goitre influence the amount of ^{131}I required, but a large nodular goitre is not a contra-indication to ^{131}I therapy unless it is causing mechanical trouble; in this situation surgery should be considered but it is not mandatory since a sufficient dose of ^{131}I will cause a very large goitre to shrink.

^{131}I therapy can be given a few days after cessation of anti-thyroid drugs, and in cases of severe thyrotoxicosis it is probably wise to induce at least some remission by drugs before a dose of ^{131}I is given. The anti-thyroid drugs can be re-prescribed 1 week after therapy.

It is of importance that successful ^{131}I therapy depends on a sufficient uptake of the dose by the gland. A check tracer uptake is a prerequisite and if it is blocked owing, for example, to iodide excess (medications, radiographic contrast media) therapy has to be postponed.

The only serious drawback to ^{131}I therapy is the high rate of hypothyroidism which is about 10 per cent at 1 year and rises to about 80 per cent at 15 years. This has led to a number of trials in which ^{131}I therapy has been modified or an alternative radionuclide, ^{125}I, has been used. Research in this area will be discussed. Methods have also been devised to follow and supervise patients treated with radioactive iodine (*see* p. 771).

SELECTION OF PATIENTS FOR ^{131}I THERAPY (1950–70)

Experience during the 1900–40 era showed that two-thirds of patients failed to recover from thyrotoxicosis and suffered either chronic relapsing morbidity or death; a third ran a fluctuating course and eventually became euthyroid (Wilson, 1967; Havard, 1969). Thus, physicians faced with a clinically thyrotoxic patient have tended to plan definitive treatment from the outset.

The choice of treatment was basically between anti-thyroid drugs for up to 2 years, anti-thyroid drugs and then operation, or ^{131}I therapy. When ^{131}I became generally available in 1946 for the treatment of thyrotoxicosis its efficacy and simplicity were quickly established in early trials (Chapman and Evans, 1946; Werner, Hamilton, and Nemeth, 1952). There were, however, real fears that the doses of irradiation used might have one or more of the following effects:—

1. Shorten the life span of the treated person by some unknown mechanism.
2. Have a somatic effect on tissues leading to thyroid and other malignancies.
3. Lead to unfavourable reproductive events and/or genetic abnormalities in the children born of treated patients.

As a consequence ^{131}I therapy was rightly confined by the majority of physicians to the following groups of patients:—

1. Patients of over 40 years of age and only in the infertile or when pregnancy was deliberately avoided.
2. Patients of less than 40 years of age in whom the life span seemed to be limited. This group included patients with diabetes and rheumatic heart disease.
3. Patients who were less than 40 years of age in whom other treatments for thyrotoxicosis had been tried but were unsuccessful, dangerous, or unacceptable. This group, who comprised in the United Kingdom about 10 per cent of all the patients treated with ^{131}I in the interval 1950–70, included patients who had an undesirable reaction to or poor control with anti-thyroid drugs. It also included those who refused or were for some good reason not fit for operation. In addition patients with thyrotoxicosis which had recurred after surgery were treated with ^{131}I.

In the United Kingdom ^{131}I therapy was very seldom used in patients of less than 25 years of age and only exceptionally in children (Macgregor, 1957). In the United States, however, some physicians did treat children and young fertile women and men. As a consequence they have been able to accumulate and to report on their experience in relation to clinical outcome, reproductive events, and genetic effects on living offspring (Starr, Jaffe, and Oettinger, 1969; Hayek, Chapman, and Crawford, 1970; Becker and Hurley, 1971; Chapman, 1971).

CALCULATION OF DOSE OF ^{131}I

^{131}I was chosen because it seemed the most appropriate on physical and radiobiological grounds; in early trials it was obviously effective. In addition, it had been released for general use and was available in large amounts at acceptable prices.

^{131}I decays with the emission of energetic beta-rays which travel up to 2200 μm. (average 500 μm.) in thyroid tissue. The beta-rays, which have a finite path, constitute more than 95 per cent of the radiation energy deposited within the thyroid. Moreover, the radiation doses immediately outside the gland fall off very sharply because of the finite paths of the beta-rays. This means that the radiation doses to tissues adjacent to the thyroid and in the neck are exceedingly small in comparison to those within the gland itself. The radiation doses given to the marrow and blood and gonads are about equal and are around 20 rad from an average effective therapy dose (Green, Fisher, Miller, and Wilson, 1961). The radiation doses to the salivary glands, stomach, and kidneys are likewise small, and a tiny fraction of that within the thyroid tissue, which during effective therapy receives an average of 10,000 rad (*see below*). ^{131}I also emits gamma-rays which travel many centimetres through the tissues and out of the body, but the contribution to the thyroid or body dose is negligible compared with that of the beta-radiation. They are, of course, the radiation used for diagnostic tracer tests, but this is another matter.

As might be appreciated, pioneers were cautious in the use of the ^{131}I therapy, starting with small single doses which were repeated until the patient became euthyroid. It soon became apparent, however, that the best philosophy was to attempt control of the thyrotoxicosis with a single drink of ^{131}I alone within 3–4 months, to shrink the thyroid when it was enlarged, and to avoid hypothyroidism if possible. It was assumed that damage in the thyroid depended on the total radiation energy deposited there—the absorbed dose (in rad).

The rad dose is dependent on a number of variables:—

1. Amount of ^{131}I given (μ.c. dose).
2. Proportion of ^{131}I taken into the gland (uptake).
3. Mass of the gland and to some extent shape.
4. Stay of ^{131}I in the gland (biological half-life).
5. Distribution of ^{131}I throughout the tissue and cells.

In turn, the net damage within the thyroid from a given radiation dose in rad depends on distribution and on cell and tissue radiosensitivity (Greig, 1965).

Dose prescription procedures had in common measurement of a tracer uptake, measurement of gland mass by palpation or more recently by scanning, and some empirical estimate of biological half-life, distribution, and radiosensitivity. Some clinicians attempted to be precise and deposit a stated radiation dose in rad within the thyroid; a typical dose was 7000 rad (Blomfield, Eckert, Fisher, Miller, Munro, and Wilson, 1959). Some accepted that this could not be possible because of uncertain variables and aimed at being accurate at getting a given amount of ^{131}I into the thyroid: a typical régime was 150 μc. per g. of thyroid (Chapman and Maloof, 1955). Other clinicians prescribed ^{131}I on an empirical basis, having gained clinical and therapeutic experience with a more rational approach such as that of Blomfield and others (1959). This experience allowed them to adjust amounts of ^{131}I for the size and nodularity of the thyroid with adjustments for factors such as the urgency for rapid control (Macgregor, 1957). It is now known that any one of the three methods gave or gives similar results (Becker and Hurley, 1971).

EFFICACY

In the early 1960's the author reviewed (Greig, 1963), in some detail, the progress of 242 patients from the start of therapy through 8 years of complete follow-up. In this group the régime was to titre the amount of ^{131}I given to deliver about 7000 rad to the thyroid (Crooks, Buchanan, Wayne, and Macdonald, 1960). The results were very similar to those reported throughout the world before (Beling and Einhorn, 1961) and after (Becker and Hurley, 1971). In the author's series 60 per cent of the patients were rendered euthyroid within 3–4 months with one dose, but a further 25 per cent required a second dose and the remainder responded to a third dose. It is of importance that all the patients were eventually rendered euthyroid within about a year and it is of equal importance that in this series, as in others (McGirr, Thomson, and Murray, 1964), the recurrence rate was negligible.

HYPOTHYROIDISM

After the patients were euthyroid, however, more and more of them became hypothyroid with progressive follow-up until after 8 years 41·3 per cent were hypothyroid and only 52·5 per cent were euthyroid; in this series the remaining 6·2 per cent were deceased or could not be traced. In the same study (Greig, 1963) a review of 134 patients who had had ^{131}I therapy after a course of anti-thyroid drugs and 59 patients who had had ^{131}I therapy for a post-operative recurrence was also carried out. The clinical outcome in these two groups of patients was substantially the same as those treated with ^{131}I from the time of presentation.

These data highlight two of the outstanding problems caused by what might be termed 'conventional' ^{131}I therapy: these are a slow rate of control and after a variable interval of euthyroidism a progressive risk of thyroid failure. It is now well established that when ^{131}I is used alone to control thyrotoxicosis it will ultimately cure the condition in every case (that is, the recurrence rate is negligible), but the sufficient amount (or amounts) of isotope given nearly always leads to hypothyroidism; the rate is 80 per cent after a 15-year follow-up. If the initial dose prescription philosophy is set at a low range the rate of control will be unacceptably slow owing to a slow response to the first dose and the frequent need for multiple doses. In this case adjuvant therapy will be required. If the initial dose prescription philosophy is set at a very high range rapid cures will be obtained in the majority of patients but the same patients will become hypothyroid at a faster rate than with conventional doses.

SAFETY

Early Effects.—No demonstrable effects have been observed referable to the recurrent laryngeal nerves, the larynx, the pharynx, the oesophagus, the salivary glands, stomach, breast, or kidneys. A few minor radiation effects are, however, occasionally encountered. Radiation thyroiditis is very rare and seldom is there more than slight discomfort; sometimes the gland may be tender and exceptionally the pain may be severe and referred to the teeth and gums. Radiation thyroiditis occurs within a few days of the treatment and settles spontaneously or very quickly with a short descending course of prednisone. Radiation sialitis producing pain and swelling in the submaxillary and parotid glands is very rare, seldom requires medication, and subsides quickly.

An exacerbation of thyrotoxicosis is very difficult to measure so that its true frequency is not known. Those of us who treat large numbers of ill patients are seldom convinced that ^{131}I therapy can cause an increased degree of thyrotoxicosis. Thyroid crisis when it does occur usually does so in people who were severely thyrotoxic before therapy. When there is a risk in, for example, those with established cardiac failure this is reduced by giving carbimazole for a few weeks before introducing ^{131}I therapy. Carbimazole depletes the gland of hormone stores and at the same time lessens the degree of thyrotoxicosis. The true incidence of an exacerbation of thyrotoxicosis is not known but in my opinion it is very unusual.

Late Effects.—No effects referable to the recurrent laryngeal nerves, the larynx, pharynx, oesophagus, breast, stomach, or kidneys have been demonstrated and the late effects, other than those of hypothyroidism, are directly concerned with the risks or otherwise of thyroid cancer, leukaemia, or undesirable genetic consequences.

Thyroid Cancer.—The United States Public Health Thyrotoxicosis Follow-up Study was started in 1961 by the National Center for Radiological Health, and they have ascertained and reported (Sheline, Dobyns, Workman, Tomkins, McConahey, and Becker, 1969) on the incidence of thyroid cancer in 22,000 patients treated over the years with ^{131}I and they have similar data from 11,000 thyrotoxic patients treated by surgery. There was no difference in the thyroid cancer rate, the rate being negligible in both groups (Sheline and others, 1969; Becker and Hurley, 1971). It would thus appear that the 10 cases of thyroid cancer reported in the literature in association with a history of ^{131}I-treated thyrotoxicosis represent remote and incidental cases (McDougall, Kennedy, and Thomson, 1971). The consensus of opinion is that ^{131}I therapy does not cause thyroid cancer if the patients treated are aged 25 years or more.

Leukaemia.—Leukaemia was one of the somatic radiation effects feared by those pioneering ^{131}I therapy (Stanbury, 1970). In the thyrotoxicosis follow-up study referred to above, data were collected from 22,000 ^{131}I-treated patients to give a patient follow-up of 119,000 years; 17 patients developed leukaemia. In 14,000 thyrotoxic patients treated by surgery there were 114,000 years of patient follow-up and 16 cases of leukaemia (Saenger, Thoma, and Tompkins, 1968). Pochin (1960) found 18 cases of leukaemia in a total of 59,200 patients treated with ^{131}I in this country and followed for a number of years. It would thus appear that the incidence of leukaemia, a condition which is unlikely to be under-diagnosed, is not increased in ^{131}I-treated patients compared with either surgically treated patients or the general population (Becker and Hurley, 1971).

Chromosome Abnormalities.—These are found in the peripheral lymphocytes of ^{131}I-treated patients (Speight, Baba, and Wilson, 1968) but not in surgically treated patients. The lymphocyte cells carrying these abnormalities persist in the circulation for many years but they do not appear to represent clones of leukaemic cells (Boyd, Ferguson-Smith, McDougall, and Greig, 1973).

Genetic and Related Effects.—Genetic effects was another major concern of the pioneers (Holcomb, 1970). This aspect was not evaluated in the United States Public Health Thyrotoxicosis Follow-up Study because of an avowed difficulty in obtaining control data, but Starr and others (1969), Hayek and others (1970), and Chapman (1971) have gone a long way to providing the necessary data. *Table I* shows data from the study of Chapman (1971) and demonstrates that reproductive events such as fertility, pregnancy, and its outcome are not influenced by successful ^{131}I therapy.

Table I.—REPRODUCTIVE HISTORY OF 103 WOMEN TREATED WITH ^{131}I (FROM CHAPMAN, 1971)

	FULL-TERM CHILDREN	PREMATURE	MISCARRIAGES
Before ^{131}I	174	11	28
After ^{131}I	142	10	27

The dose to the ovaries after successful ^{131}I therapy is about 17 rad. In a group of more than 300 children above 3 years of age born of parents (male or female) treated at any age with ^{131}I, 219 have been seen and the incidence of disease determined. These data (Chapman, 1971) when analysed against the actuarial risks of congenital abnormalities, which for the whole population seem to be about 4 per cent of all live births, show a miniscule increase in the average risk of birth defects which might reasonably be attributed to ^{131}I therapy. This reassuring information is similar to that reported (Hayek and others, 1970) for treated females; 12 who were given ^{131}I therapy before the age of 18 gave birth to 18 normal children. Starr and others (1969) treated 73 children with ^{131}I many years ago and now find that the 28 females in the series eventually gave birth to 52 normal children.

The effects of ^{131}I therapy on the germ cells of individuals or the population as a whole can be looked at in another way. The International Commission on Radiological Protection, reporting in 1966, estimated that for each rad of parenteral gonad radiation above background the risk of producing a child with a transmissible trait is 1·6 per 100,000 live births. When patients are rendered euthyroid with ^{131}I the ovaries receive on average 16·6 rad (Weijer, 1964). The spontaneous incidence of these anomalies is about 0·8 per cent, so that ^{131}I therapy will increase the risk by not more than 0 025 per cent (Becker and Hurley, 1971).

Most mutations are, however, recessive and are not expressed in the first generation. The concept 'genetic death' is used to evaluate the effects of mutations on future generations. Genetic death is 'the extinction of a gene lineage through the premature death or reduced fertility of some individual carrying the gene' (Crow, 1957). It is estimated that if each member of the parental generation received 1 rad to both gonads there would be an increase of 0·1 per cent in the genetic deaths occurring in each generation for the next 10 generations (International Commission on Radiological Protection, 1966). Means, De Groot, and Stanbury (1963) think that the incidence of hyperthyroidism is 0·02 per cent per year or 1·4 per cent in a normal lifetime. If 50 per cent of thyrotoxicosis occurred during child-bearing years and if they all received ^{131}I therapy the average gonadal dose to the population would be $0{\cdot}014 \times 0{\cdot}5 \times 16{\cdot}6 = 0{\cdot}116$ rad. This would increase the incidence of genetic death by roughly 0·01 per cent per generation. Radiation from natural background is about 100 mrad per year and X-rays add another 55 mrad to this (Brown, Roney, and Hilberg, 1968). It would thus appear that the use of ^{131}I therapy in younger people is unlikely to increase the prevalence of transmissible genetic defects in succeeding generations.

^{131}I Therapy during Pregnancy.—Effects arising from ^{131}I given during pregnancy should, of course, not be amenable to study since pregnancy is an absolute contra-indication to this treatment. Nevertheless, the population currently receiving therapy is predominantly female, some of whom are fertile and occasionally pregnant without knowing it. Foetal hypothyroidism has been reported on 6 such occasions as reviewed by Pfannensteil, Andrews, and Brown (1965) and McDougall (1972). Usually, however, the baby is otherwise perfectly healthy (Silver, 1968). In fact, more often than not the baby is completely unaffected, although one would presume that if the foetal thyroid was irradiated there would be an increased risk of thyroid cancer in later life.

Abnormalities of Calcium Metabolism.—Damage to thyroid 'C' cells has been suspected after ^{131}I therapy. Certainly 'C' cells resident in the thyroid must be destroyed in the long term as the thyroid atrophies. ^{131}I-treated patents do tend to dispose of an intravenous calcium load at a slower rate than normal people or untreated thyrotoxic patients (Williams, Hargis, Galloway, and Henderson, 1966) and the effects seem to increase as the thyroid atrophies. Nevertheless, plasma-calcitonin levels are normal in patients without thyroid tissue (Gudmundsson, Galante, Woodhouse, Matthews, Osafo, McIntyre, Kenny, and Wiggins, 1969), and in untreated and treated thyrotoxics the serum-calcitonin levels are the same as in healthy people (Fraser and Wilson, 1971). It is true that in females thyrotoxicosis produces a relative demineralization of bone but this apparently decelerates as the hyperthyroidism is controlled, whether by ^{131}I, operation, or anti-thyroid drugs (Fraser, Smith, Anderson, and Wilson, 1971).

Damage to the parathyroids is a possibility during ^{131}I therapy. Very rarely, relative hypocalcaemia, spontaneous or induced by stress tests (Better, Carty, Brautbar, and Barzilac, 1969), has been reported after ^{131}I therapy, an effect attributed by some to radiation loss of parathyroid reserve (Eipé, Johnson, Kiamko, and Bronsky, 1968). In practice, however, neither blood-calcium levels nor bone density seems to be any different in age- and sex-matched patients treated by ^{131}I therapy and compared with those treated by anti-thyroid drugs (Fraser and others, 1971). It can, therefore, be stated that ^{131}I destruction of the thyroid does not result in significant abnormalities of calcium metabolism.

^{131}I THERAPY—THE CURRENT POSITION

^{131}I is still the isotope of choice. Recent evidence shows that it has no side-effects even when used in young adults, apart from the inevitable hypothyroidism. This being so, several questions should now be posed and answered:—

Which patients should be treated with ^{131}I?
What should the dose philosophy be?
What steps should be taken to supervise follow-up?
When is a patient hypothyroid?
What is the treatment for hypothyroidism?

Which Patients should be treated with ^{131}I?—The indications for ^{131}I therapy need to be reviewed now that we know that it is safe. All patients over 40 years of age should continue to have ^{131}I therapy by choice and without doubt the elderly, frail, and those with associated disorders, such as atrial fibrillation and cardiac failure. The size and nature of the thyroid should not influence this decision except that operation might be considered when the goitre is exceptionally large, causing mechanical trouble, or is retrosternal. In the author's opinion, however, even the largest glands will shrink provided that enough ^{131}I is given. There is now no doubt at all that ^{131}I therapy is indicated for a postoperative recurrence of thyrotoxicosis (McLarty, Alexander, Harden, and Clark, 1969) irrespective of the patient's age, sex, or fertility, provided, of course, that pregnancy is excluded at the time of therapy and avoided for up to 1 year after successful control. There is also much less reluctance to use ^{131}I therapy in young patients who have experienced a reaction to initial drug therapy. The alternatives are to change to another drug such as from carbimazole to propyl thio-uracil (Wilson, 1967; Havard, 1969) and to plan operation. The author's view is that this group should have ^{131}I therapy since the morbidity is less than that from surgery. The presence of significant titres of serum-anti-thyroid antibodies is not a contra-indication to ^{131}I therapy and, in fact, probably makes the case for it stronger. It is known that serological evidence of auto-immune thyroiditis increases the risk of post-operative hypothyroidism by a substantial fraction (Irvine, Macgregor, and Smart, 1962). Similarly, patients who for some good reason are not obtaining control from drug therapy or who relapse after a course of anti-thyroid drugs given for 1–2 years (50 per cent relapse) should have ^{131}I therapy rather than operation.

Patients of less than 40 years of age with a large gland have in the past been treated in this country by surgery, but this approach is not universal. Some clinics in the United States seldom refer any thyrotoxic patients for surgery and have experience in either controlling patients with anti-thyroid drugs on a long-term basis or referring them for ^{131}I therapy (Hershman, Givens, Cassidy, and Astwood, 1966).

Certainly the total morbidity from surgery may add up to as much as 50 per cent (McNeill and Thomson, 1968; Editorial, 1970), and perhaps if anti-thyroid drugs and ^{131}I therapy had been introduced in the 1920's surgery would seldom have been indicated in the management of thyrotoxicosis. On the other hand, expert surgeons may safely render a large proportion of patients euthyroid and they remain so provided that there is no auto-immune thyroiditis.

There are now very few absolute contra-indications to ^{131}I therapy. Thyrotoxicosis at birth or shortly afterwards and thyrotoxicosis in pregnancy certainly should not be treated with radiation. Similarly, thyrotoxicosis in children and young adults should first be treated with anti-thyroid drugs and if this is not satisfactory by surgery or ^{131}I therapy. It is well to remember, however, that the results of surgery in children are not very good (Saxena, Crawford, and Talbot, 1964; Havard, 1969) and there is a place for ^{131}I therapy here too, since it does not seem to affect fertility, pregnancy, or its outcome (Chapman, 1971).

What should the Dose Philosophy be?—The details of treatment are, of course, the province of the specialist in nuclear medicine or radiotherapy working in close collaboration with an endocrinologist. ^{131}I therapy should be organized on a regional basis with a central facility for patient assessment, dose calculation and prescription, and follow-up.

In the elderly, frail, and those with diabetes, heart disease, rheumatoid arthritis, atrial fibrillation, and cardiac failure, for example, a large dose designed to destroy the gland quickly should be given. The author now uses doses twice those advocated by Macgregor in 1957. If there is some risk of increasing the severity of the hyperthyroidism a course of carbimazole in a dose of, say, 15 mg. every 6 hours can be given for a few weeks. This has the merit of initiating some control and depleting the gland of hormonal stores. The technique is to stop the carbimazole for 1 week, measure thyroid uptake by tracer, assess thyroid mass, and prescribe a large amount of ^{131}I. Some loading of the dose is probably necessary in this category of patients (Crooks and others, 1960). Carbimazole can be recommended 1 week after the ^{131}I has been given in an amount of about 5 mg. every 6 hours, but a careful watch must, of course, be kept for the rapid onset of hypothyroidism. Deliberately large doses of ^{131}I should also, in the author's opinion, be prescribed for younger patients who have suffered prolonged or fearsome morbidity due to a postoperative recurrence, drug reaction, poor control with drugs, or relapse after a long course of drugs.

How should we use ^{131}I in patients who have, however, uncomplicated thyrotoxicosis? This group comprises mainly the relatively fit thyrotoxic in the 40–60-year age range or indeed in young patients, depending on treatment philosophy. Most of these patients have moderately enlarged thyroids. There are two possible approaches here and each has its supporters. They may be summarized as follows:—

1. Give large doses of ^{131}I from the start, anticipate hypothyroidism, and either give replacement therapy at about 1–2 months or when the criteria for hypothyroidism are satisfied (*see below*).

2. Give small doses of ^{131}I and expect only a small proportion to become euthyroid at 3 months. If at 3 months the patients are still thyrotoxic, and on the assumption that ^{131}I will gradually create a progressive effect and the disorder will remit, give non-destructive anti-thyroid drugs or symptomatic therapy. In practice, this means adding either carbimazole in a dose of 5 mg. three or four times a day (Smith and Wilson, 1967) or iodides in a dose of potassium iodide, 30 mg. three times a day (Hagen, Quellette, and Chapman, 1967), or propranolol in a dose of about 20 mg. four times a day provided that there are no contra-indications (Hadden, Shanks, Montgomery, and Weaver, 1968).

Of the three adjuvant treatments the author's preference is for carbimazole. Smith and Wilson (1967) used carbimazole in this way. They found, however, that 64 per cent of patients treated with 3500 rad from ^{131}I required drug treatment for a few months but 5 years later, when all drugs had been discontinued, only 7 per cent were hypothyroid. It is interesting that no case given ^{131}I therapy and drugs became hypothyroid. The approach of Smith and Wilson (1967) could be combined with the suppression test described by Alexander, Harden, Shimmins, McLarty, and McGill (1967). If after a small dose of ^{131}I followed by carbimazole for some months thyroid-uptake suppressibility returns there might be a case for stopping the anti-thyroid drugs with a reasonable expectation of a permanent remission. The approach outlined does reduce the incidence of hypothyroidism to very low levels. The relapse rate is also less than that encountered in surgical cases (Wilson, 1967).

What Special Steps should be taken to supervise Follow-up, diagnose Hypothyroidism, and treat it?—*See* contributions by Hall (not published here) and Hedley, p. 771.

Special Problems.—

1. *Poor Thyroid Uptake of Therapy Dose.*—Potassium perchlorate stops iodide trapping so that the occasional patient who is taking this drug temporarily as a substitute for one of the thio-uracils or imidazolines must stop it for at least a week before ^{131}I therapy is planned.

Patients who have taken stable iodides or iodine either intentionally or accidentally pose a special problem because the thyroid uptake of tracer and therapeutic dose is blocked. The degree of blockage and the time that it takes for recovery obviously depend on the amounts, character, route, and duration of the iodide excess. Although the therapeutic dose can be adjusted to take account of very low thyroid uptakes, there is not much point in using this therapy unless the thyroid takes up at least 25 per cent of the dose. There is no easy way of discharging stable iodide from the gland, but in thyrotoxicosis the best that can be done is to prescribe anti-thyroid drugs and at a later date, perhaps a few months, these can be stopped. If after a week the radio-iodine tracer uptake is 25 per cent or more ^{131}I therapy can be prescribed.

2. *Very Large Goitres.*—A very big thyroid is not a contra-indication to ^{131}I therapy but treatment of such patients raises two issues: the amount of the therapy dose and the risk of an exacerbation of thyrotoxicosis owing to the bulk of the tissue being irradiated and the possibility of releasing stored hormone into the circulation. A nodular thyroid of 100 g. in an ill patient might require 50 μ.c. of ^{131}I or more. There is not much to be gained from pretreatment with drugs in this situation since the gland may increase in size and the drugs may at any rate induce relative radioresistance (Crooks and others, 1960). In this situation it is important to ensure that any complications such as atrial fibrillation and cardiac failure are firmly treated before ^{131}I is given. Similarly, if the patient has no cardiac problems, asthma, or glaucoma, propanolol may be prescribed to subdue any slight exacerbation of hyperthyroidism. If there is a serious risk of exacerbation of hyperthyroidism there is no reason why the therapy could not be divided into, for example, two doses of 25 μ.c. separated by an interval of 1 month.

3. *Radiation Risks to Others.*—Some ill patients are, of course, treated in hospital and they should be placed in a side-room and the advice of the radiation safety officer sought. In general though, simple precautions suffice. These include a radiation sign on the door, lead aprons, and advice that the patient flushes the toilet several times. After a week no special precuations are required; no children should be allowed to visit during that week. If the patient has urinary incontinence she should be catheterized. If the patient vomits or soils the bedclothes these should be collected by the radiation safety officer for incineration.

The radiation hazard to relatives and the public arising during ^{131}I therapy of an out-patient has been discussed by the International Commission on Radiological Protection (1966) and more recently by Buchan and Brindle (1971) and Pochin (1972). It is estimated that a husband might be expected to receive about 30 rad for every μ.c. of ^{131}I given to his thyrotoxic wife; walking children receive much less. A working rule is that a patient receiving more than 30 μ.c. ^{131}I should be in hospital in a special room for up to 1 week; thereafter the patient may return home. No special precautions are required at home, but in general the patient should avoid contact with pregnant contemporaries and with young children for the first week.

4. *Exophthalmos*.—The link between thyrotoxicosis due to Graves' diesase and exophthalmos has not been fully identified. The balance of opinion is against an association with long-acting thyroid stimulator (Munro, 1971), but Kriss, Pleschakou, Rosenblum, Holderness, Sharp, and Utiger (1967) studied the progress of eye signs in patients treated with ^{131}I. Serial serum long-acting thyroid stimulator titres and serum anti-thyroglobulin antibody titres showed a rise in those whose eye signs deteriorated following this therapy. Others, however, have not found this (Munro, 1971). Kriss (1970, 1971) believes that energetic ^{131}I therapy does tend to lead to a deterioration in the ophthalmopathy when it is significant at the start of treatment. The mechanism for this, he believes, may lie in some common immunological link between thyroid antigen and an antigen in one or all of the extraglobal intra-orbital tissues.

In practice, ^{131}I therapy given to people with uncomplicated moderate exophthalmos leads to a slight increase in this during initial control and is similar to the increase following anti-thyroid drugs (Greig, Mohammed, Aboul-Khair, and Crooks, 1965). However, in the small minority of patients whose eye signs are severe or progressive it is probably wise to avoid ^{131}I therapy because of the anxieties expressed by Kriss (1970, 1971). Certainly the induction of hypothyroidism in this group of patients has a deleterious effect on the ocular signs; flexible anti-thyroid drug treatment is preferable. Incidentally it was at one time thought that total thyroid destruction by removing some speculative but unknown antigen in the thyroid might lead to an improvement in severe ophthalmopathy. This theory has now been discounted in practice as shown by studies of Boyle, Greig, Thomson, Winning, and McGirr (1969) and Volpé, Desbarats-Schonbaum, Schobakm, Row, and Egrin (1969). The specific management of the eye signs are, of course, a special problem and a decision about corticosteroid therapy or orbital decompression must in general be taken independently of the treatment for the hyperthyroidism.

THE SURGICAL MANAGEMENT OF THYROTOXICOSIS

BY C. A. S. PEGG,* D. J. STEWART, P. D. BEWSHER, AND W. MICHIE
THE JOINT THYROID CLINIC AND UNIVERSITY DEPARTMENT OF THERAPEUTICS, ABERDEEN ROYAL INFIRMARY

SUMMARY

Preparation of selected thyrotoxic patients for partial thyroidectomy can be safely and quickly achieved using propranolol, the duration of preoperative therapy and the number of out-patient attendances being reduced by over 50 per cent. No problems have been encountered during preparation or intraoperatively in patients pretreated with propranolol when compared with patients pretreated with conventional preparations. The commonest form of morbidity following destructive therapy for thyrotoxicosis is hypothyroidism. In surgically treated patients hypothyroidism can be defined within 1 year of operation. The factors influencing postoperative hypothyroidism are discussed.

PARTIAL thyroidectomy has for many years been an established form of treatment for thyrotoxicosis. Refined anaesthetic and surgical techniques have reduced operative and perioperative mortality to virtually nil. Certain forms of morbidity, however, persist and though the incidence of complications such as wound haemorrhage, nerve injury, and hypocalcaemia are now less significant, hypothyroidism following surgery remains a major and possibly *the* major complication. Hypothyroid rates have been variously recorded as 3·3 per cent (Riddell, 1962) and 4·5 per cent (Cattell, 1949), but more recent studies have shown rates of 35 per cent (Hedley, Flemming, Chesters, Michie, and Crooks, 1970) and 48 per cent (Beahrs and Sakulsky, 1968).

The great variation in these figures is difficult to understand, but it is possible that the higher figures may merely represent a more critical evaluation of postoperative thyroid status. Historical evidence of the behaviour of untreated thyrotoxicosis does suggest that the higher recorded incidence of postoperative hypothyroidism may be more realistic. Studies at the turn of the century (*Table I*) indicated that approximately 20 per cent of untreated thyrotoxic patients died acutely in crisis while 40 per cent pursued a chronic course of exacerbation and remission into thyrocardiac disability. Approximately 40 per cent of untreated thyrotoxic patients ultimately improved spontaneously (Williamson, 1896; Ord and Mackenzie, 1897; Mackenzie, 1905; Sattler, 1908; Campbell, 1921), and while some remained euthyroid, others lapsed into hypothyroidism over the course of several years (Baldwin, 1895; Campbell-Gowan, 1895; Sattler, 1908). It would seem, therefore, that in some thyrotoxic patients there is a naturally progressive thyroid impairment leading to decreased reserve of function or frank failure, and it may be that in these patients surgery merely accelerates the natural course of the disease, compressing the events of many years into a matter of months.

SCOPE OF THE STUDY

The enigmatic and unpredictable appearance of hypothyroidism in some of the untreated thyrotoxic patients is mirrored in the postoperative behaviour of thyrotoxic patients who have been treated surgically. The present position is that though a reasonable estimate of the incidence of hypothyroidism can be made for a group of patients, the fate of individual patients can be predicted only within wide limits (Michie, Pegg, and Bewsher, 1972). In an endeavour to determine the factors which might influence the development of hypothyroidism after surgery and which might be of value in determining its early diagnosis and subsequent management, we have studied 373 patients who were subjected to surgery for thyrotoxicosis during the years 1965–71 inclusive. Hypothyroidism was assessed by a standard clinical diagnostic index (Billewicz, Chapman, Crooks, Day, Gossage, Wayne, and Young, 1969), on electrocardiographic evidence, and on serial serum protein-bound ^{127}I and cholesterol estimations. Patients were reviewed at 1, 4, and 12 months after operation and thereafter on a yearly basis until the services of a computer-assisted register became available (Hedley, Scott, Weir, and Crooks, 1970). The factors that were examined were preoperative preparation, surgical management, and early postoperative behaviour. Preoperative preparation in the earlier years was along conventional lines using carbimazole and Lugol's iodine. In the later years propranolol was employed, initially in conjunction with carbimazole but later on its own, excluding conventional preparations. More recently still, patients have been operated upon after a short course of propranolol, sometimes of a week's duration, and without preoperative Lugol's iodine.

We became acutely aware of the importance of the thyroid remnant size, as indicated by the high incidence of hypothyroidism in the early years of the study (*Table II*). This led from mid-1967 to a policy of leaving larger remnants with a resulting decrease in the hypothyroid rate to around 30 per cent.

---

* Present address: General Hospital, Nottingham.

The factors of age, blood-group, anti-thyroid drug influence, and anti-thyroid antibody titres determined preoperatively have also been studied in relation to subsequent behaviour.

Percentage hypothyroid	40	48	51	52	47

* Fifty-three patients received propranolol and have been excluded

RESULTS

Factors not influencing Hypothyroidism.—The duration of anti-thyroid drug therapy varied from a month to several years, and usually was determined by the physicians who supervised the preoperative care of the patient. No correlation was found between postoperative hypothyroidism and the duration of treatment (*Table III*), nor did the amount of drugs prescribed affect the incidence of hypothyroidism (*Table IV*). The titre of anti-thyroglobulin antibodies (Fulthorpe, Roitt, Doniach, and Couchman, 1961) measured preoperatively was higher in hypothyroid patients, but this difference did not reach statistical significance. Preoperative anticytoplasmic antibody (Beck, 1971) was equally prevalent in hypothyroid and euthyroid patients (*Table V*). Despite considerable variation in the size of the thyroid glands (65 weighed less than 30 g., 40 more than 100 g.) no relationship between total gland mass and hypothyroidism could be demonstrated (*Table IV*).

Factors influencing Hypothyroidism.—A study of the blood-group distribution of thyrotoxic patients in this study showed the distribution of ABO blood groups to be almost identical with the general population of the North-east region of Scotland (Mourant, Kopec, and Domaniewska-Sobczak, 1958) (*Table VII*). Blood-group O was significantly more common in the hypothyroid group of patients ($P<0\cdot05$). Blood-group A was less common but this difference did not reach statistical significance ($0\cdot05<P<0\cdot1$; *Table VIII*). Postoperative hypothyroidism also showed a higher incidence in female patients over the age of 40 years who were pretreated with carbimazole than in the younger age-group ($P<0\cdot05$; *Table IX*).

Table IV.—INCIDENCE OF HYPOTHYROIDISM IN RELATION TO TOTAL AMOUNT OF ANTI-THYROID DRUG PRESCRIBED

Hypothyroid	69	47	18	17	151
Percentage hypothyroid	45	47	62	47	47

* Fifty-three patients received propranolol and have been excluded.

The most significant factor which determines the behaviour of a group of patients after partial thyroidectomy is the size of the remnant left at operation. Remnants of 4 g. or less carry the highest hypothyroid rate, whereas those of 10 g. or more carry the lowest ($P<0\cdot001$; *Table X*). It must be emphasized, however, that the size alone is not the only criterion, for with a remnant size of 4 g. or less there is a 36 per cent incidence of euthyroidism while with a remnant of 10 g. or more hypothyroidism still occurs in 20 per cent of patients.

MANAGEMENT

What advice can be offered in the avoidance of postoperative hypothyroidism? Although the 'ideal' remnant size must remain conjectural for the individual patient, average remnant size for the group should be in the region of 7–9 g. It would also seem logical to leave larger than smaller remnants in patients who belong to blood-group O and in female patients of over 40 years of age. Against this we have found unhelpful the response to anti-thyroid drug therapy, either in the duration of treatment or in total dosage. Our findings also suggest that antithyroid antibody titres should not influence the decision on remnant size.

Table V.—RELATIONSHIP BETWEEN ANTI-THYROID ANTIBODIES DETERMINED BEFORE OPERATION AND INCIDENCE OF HYPOTHYROIDISM

* Female patients prepared with carbimazole only.

The surgeon, like the radiotherapist, must accept a measure of post-treatment hypothyroidism, and for the surgeon the figure is unlikely to be less than 30 per cent. Whichever the method of treatment there is a clinical and ethical responsibility for the continuing supervision of these patients. It has been our practice to estimate protein-bound ^{127}I levels at 1 and 4 months after operation and thereafter yearly. From a study of 1- and 4-month figures a distinct pattern emerges. When both levels are 4 μg. per 100 ml. or more we have not observed hypothyroidism in the subsequent follow-up period. Where both levels are below 4 μg. per 100 ml. there is a 77 per cent incidence of hypothyroidism. When one of these levels is below 4 μg. per 100 ml. the incidence of hypothyroidism is around 20 per cent, but a rising level holds a more favourable prognosis than a falling one ($P < 0{\cdot}001$; *Table XI*).

Contrary to published reports (Nofal, Beirwaltes, and Patno, 1966; Olsen, Nishiyaric, and Graber, 1970), we have not observed hypothyroidism occurring later than 1 year after operation. Thus within 1 year it becomes possible to define the thyroid status of an individual patient. Approximately 70 per cent will be euthyroid, while the remaining 30 per cent will require thyroxine replacement. This is a matter of some importance for the busy surgeon for whom a computer-assisted register may not be available. Although ideally all patients subjected to surgery merit lifelong supervision, the surgeon can concentrate his attention on those patients whose early postoperative protein-bound ^{127}I levels have been less than 4 µg. per 100 ml.; in this respect the surgeon has an advantage over his medical colleagues.

	PROPRANOLOL	CARBIMAZOLE
Mean No. of out-patient attendances	4	9
Mean duration of treatment (d.)	46	314

A further advantage in management will accrue to the surgeon from the use of the beta-adrenergic blocking agent propranolol. The ability of propranolol to control the haemodynamic changes of hyperthyroidism has been recorded (Rowlands, Howitt, and Markman, 1965; Turner, Granville-Grossman, and Smart, 1965; Howitt and Rowlands, 1966; Parsons and Jewitt, 1967; McDevitt, Shanks, Hadden, Montgomery, and Weaver, 1968; Shanks, Hadden, Lowe, McDevitt, and Montgomery, 1969), and an improvement in other symptoms and signs has also been demonstrated (Marsden, Gimlette, McAllister, Owen, and Miller, 1968; Pimstone, Marine, and Pimstone, 1968; Shanks and others, 1969). The use of propranolol as a preoperative agent has also been described (Barroso and Laczano, 1968; Vinik, Pimstone, and Hoffenberg, 1968 Granger, Wolf, and Strazielle, 1969; Shanks and others, 1969; Giardina, Bellotti, De Gregori, and Ghidiri, 1971; Turner, 1971). We have used it in approximately 100 patients; in 50 propranolol was used in conjunction with carbimazole, whilst in the remainder preparation was by propranolol alone *Table XII* compares patients treated concurrently, either with carbimazole or propranolol in respect of preoperative out-patient attendance and duration of treatment. In both respects propranolol seems to offer considerable advantages. The use of propranolo in the preoperative management of thyrotoxic patients is still under joint evaluation by physician surgeon, and anaesthetist, and we have been carefu to exclude patients with a history of bronchospasm and myocardial decompensation. In patients where propranolol has been employed there have been no problems during preoperative preparation or intra-operative complications for either the anaesthetist or the surgeon. With increasing confidence in its use we have reduced the duration of preoperative preparation and more recently several patients have come to operation within 10 days of commencement of treatment, the shortest being 3 days, and withou the use of preoperative iodine. With experience it should be possible to operate on the florid thyrotoxic patient after a preoperative course of a week or less.

Present indications are that the incidence of postoperative hypothyroidism is the same after propranolol as after conventional therapy. The curtailment of preoperative preparation that propranolol allows and the ability to define postoperative thyroid status for the individual patient within a year offers considerable advantages for the surgically treated thyrotoxic patient.

LYMPHOID TISSUE IN THE THYROID GLAND AND THYMUS OF PATIENTS WITH PRIMARY THYROTOXICOSIS

Summary

The amount of lymphoid tissue in the thyroid gland and thymus at the time of partial thyroidectomy was measured quantitatively with the point-counting technique.

The normal pattern of age involution of the thymus was established in patients with non-toxic nodular goitre. In all the patients with thyrotoxicosis the thymus is hyperplastic; after pretreatment with anti-thyroid drugs, such as carbimazole, the pattern of age involution is similar to that in the control subjects, whereas after propranolol therapy very little age involution is seen. Patients treated with anti-thyroid drugs show much less lymphoid infiltration of the thyroid gland than those prepared with propranolol.

There is good historical evidence that the thymus is enlarged in patients dying with untreated primary thyrotoxicosis and this feature was apparently so prominent that unsuccessful attempts were made to treat the disease by thymectomy at the beginning of this century (Fisher, 1964). More recently, it has been shown that the thymus is enlarged (Irvine and Sumerling, 1965) and hypertrophied (Michie, Beck, Mahaffy, Honein, and Fowler, 1967) during life in primary thyrotoxicosis patients in whom the disease activity had been controlled with anti-thyroid drug treatment. Focal thyroiditis formed of aggregates of lymphoid cells is a not infrequent finding in the thyroid gland of patients with primary thyrotoxicosis; there is evidence that in patients prepared for subtotal thyroidectomy with anti-thyroid drugs, such as methyl thio-uracil and carbimazole, those with extensive lymphoid infiltrate in the thyroid gland at the time of operation are much more likely to become hypothyroid after the operation than those with little thyroiditis (Greene, 1950–1; Levitt, 1951).

In view of these indications of an abnormality of the lymphoid tissues in primary thyrotoxicosis and the evidence that auto-immunity complicates and may in fact be responsible for the thyroid hyperfunction in this disease, the present investigation was undertaken to determine quantitatively the changes in the fixed lymphoid tissue in the thyroid gland and thymus in this disease. Since some of the patients had been prepared for operation with carbimazole and others with propranolol, we were able to compare the influence of these drugs on the fixed lymphoid tissues in this disease. This paper reports our preliminary findings.

METHODS

Conventionally fixed and stained sections of thyroid gland and thymus removed at operation were studied with the point-counting technique which allows calculation of the relative volumes of various tissue components in these organs (Dunnill, 1968). With a graticule fixed in the eyepiece of the microscope, the number of appositions of the graticule on particular tissue components was counted in every field examined. The whole of the section of each thymus was counted field by field, and the cumulative total of appositions on thymic parenchyma (and its components, cortex, and medulla) and on the intervening stroma was determined. The ratio of these counts gives an accurate estimate of the relative volumes of these components in the whole organ. The area of the thyroid gland sections was much greater, and consequently fields were selected using six-figure random numbers to define the co-ordinates of the mechanical stage and the counts were continued until the standard error of the observations was less than 5 per cent.

RESULTS

Histometry of the Thymus.—

Non-toxic Nodular Goitre.—In an attempt to define the pattern of age involution in patients who do not have evidence of immunological disease, thymic biopsies from 89 patients (51 women and 38 men) undergoing thyroidectomy for this disease were studied. The lymphoid parenchyma in the thymus declines from about 50 per cent in late teenage to about 10 per cent in late middle age. There is a striking sex difference; in men age involution is linear, whereas in women it is biphasic owing to a 'hump' in the first half of the fifth decade. The sex difference is due entirely to a difference between the cortex in the two groups.

Primary Thyrotoxicosis in Patients prepared for Operation with Anti-thyroid drugs.—One hundred and thirty-one female patients were studied. In these patients the thymus is hyperplastic, but the pattern of age involution of the whole parenchyma is similar to, but at a higher level than, that in non-toxic nodular goitre patients. The main difference between these two groups of patients is the much more abundant medulla in the thyrotoxic patients.

Primary Thyrotoxicosis in Patients prepared for Operation with Propranolol.—Twenty-seven female patients were studied. These patients show little evidence of age involution of the thymic parenchyma and the findings are spectacularly different from age-matched anti-thyroid drug patients ($P < 0{\cdot}001$); this difference is largely explained by the more prominent hyperplasia of the cortex in the propranolol-treated patients.

Histometry of the Thyroid Gland in Treated Primary Thyrotoxicosis.—When the thyroid glands of the 131 female patients treated with carbimazole were compared with those of the 27 women treated with propranolol, no histological features were noted in either group that were absent from the other group. The glands in both treatment groups showed the well-documented features of treated primary thyrotoxicosis, such as epithelial hyperplasia, small acini, and colloid depletion. Thus there was no absolute difference in the qualitative histological appearances between the two groups.

Histometry showed that there were minor differences between the two groups in the proportion of the gland occupied by epithelial cells and colloid: the thyroid glands of the propranolol patients were marginally 'more florid'. The most marked difference between the two groups was that lymphoid infiltrate was more frequent and in general more abundant in the propranolol-treated patients than in the carbimazole group; the distributions were not normal, but a Willcoxon test showed that the difference between the two treatment groups was highly significant ($P < 0{\cdot}001$).

DISCUSSION

The enlargement of the fixed lymphoid tissues in the thyroid gland and thymus of untreated primary thyrotoxicosis patients is a marked feature of the disease. It is likely that this is at least partly due to the stimulatory effect of raised circulating thyroid hormone levels since lymphoid hyperplasia can be induced in experimental animals by feeding thyroxine. This is probably not the only influence, since thymic hypertrophy is a feature of certain auto-immune diseases, such as myasthenia gravis where the patients are euthyroid and here the lymphoid infiltrate in the thyroid gland probably indicates active destructive auto-immunity.

Our measurements have shown that the thyroid gland is enlarged and also hypertrophied in patients with treated primary thyrotoxicosis. After carbimazole treatment the medulla is proportionately larger, but the thymus shows a normal pattern of age involution; after propranolol treatment both the cortex and the medulla are enlarged and little age involution is seen. Lymphocytic infiltration is present in the foci of chronic thyroiditis in the two treatment groups and this is much more prominent in the thyroid glands of patients treated with propranolol.

The marked differences between the amounts of fixed lymphoid tissue in the thyroid gland and thymus of the primary thyrotoxicosis patients treated with carbimazole and propranolol may be related to the pharmacological action of these drugs. The conventional anti-thyroid drugs reduce thyroid function and so make the patient euthyroid. By contrast, propranolol is a β-adrenergic blocking agent that can neutralize the effects of raised circulating thyroid hormone levels on cardiovascular receptors. Consequently, the most plausible explanation of our findings would be that the lymphoid tissues in carbimazole-treated patients have been released from excessive thyroid hormone stimulation and have partly reverted to normal by the time of operation, whereas the lymphoid tissues in propranolol-treated patients continue to be subjected to excessive thyroid-hormone stimulation.

Two other explanations for our findings should be considered. First, it is possible that the conventional anti-thyroid drugs have immunosuppressive properties in view of their chemical similarity to uracil, but this pharmacological action has not been investigated (Berenbaum, 1973); if this were so, then it would be possible that this action would induce lymphoid tissue atrophy in the patients treated with carbimazole. Secondly, it is remotely possible that propranolol could cause hyperplasia of lymphoid tissues by direct stimulation, but this explanation is unlikely since the appearances of the lymphoid tissues in propranolol-treated patients are similar to the historical pathological descriptions of untreated primary thyrotoxicosis.

Primary thyrotoxicosis is a complicated disease in which it is probable that immunological and endocrinological mechanisms interact. It is possible that investigation of the pharmacological effects of the drugs used in its treatment will assist the understanding of the pathogenesis of the diseases.

LONG-TERM AFTERCARE FOR PATIENTS TREATED FOR THYROTOXICOSIS

BY ANTHONY J. HEDLEY

FELLOW IN COMMUNITY MEDICINE, SCOTTISH HEALTH SERVICE, AND DEPARTMENT OF SOCIAL MEDICINE, UNIVERSITY OF EDINBURGH

THE CLINICAL PROBLEM

THE nature and magnitude of the clinical problem of providing effective aftercare for patients with thyroid disease can be clearly defined.

Destructive Therapy.—All the patients treated with radioactive iodine for thyrotoxicosis remain at risk of developing hypothyroidism within their lifetime (*Table I*), and patients treated surgically carry the double risk of either early hypothyroidism or late-onset recurrent hyperthyroidism (*Table II*).

Table I.—RESULTS OF FOLLOW-UP STUDIES AFTER ^{131}I THERAPY

AUTHOR	MAXIMUM FOLLOW-UP PERIOD (yr.)	PERCENTAGE OF PATIENTS WHO WERE HYPOTHYROID
Cassidy and Astwood (1959)	8	26·0
Beling and Einhorn (1961)	7	26·5
Burnett and others (1962)	7	16·5
Green and Wilson (1964)	10	29·0
McGirr and others (1964)	1½	17·2
Crooks (1965)	8	41·3
Hagen and others (1967)	—	33·0
Smith and Wilson (1967)	5	29·0

Anti-thyroid Drugs.—This form of treatment, which is simple, cheap, and effective and leaves the gland intact, is preferred by many clinicians and also undoubtedly by their patients. Although many patients achieve a prolonged remission, particularly when their response to treatment is monitored by the assessment of thyroid suppressibility, all the patients remain at risk of a recurrence at a later and unpredictable point in time.

Thyroxine Replacement Therapy.—There is clear evidence from several follow-up studies that the prescription of replacement therapy for patients with spontaneous or iatrogenic hypothyroidism does not provide infallible protection against the future development of hypothyroidism.

The actual numbers of patients involved on a national scale can only be estimated with difficulty because of the inadequacy of our records systems. Many patients are investigated and treated solely on an out-patient basis. Out-patient departments invariably lack a comprehensive diagnostic index facility and unless separate registers are kept for all patients with thyroid disease then much vital information is lost. It can be shown, however, that in countries such as the United Kingdom and United States the number of new patients at risk of iatrogenic thyroid disease lies between 10,000 and 30,000 a year. It is clear that the health services should be able to provide effective medical care in response to such a specific need.

It is important to emphasize that the reported results of treatment in many centres have only been realized after *ad hoc* retrospective surveys have been carried out. This is an extremely unsatisfactory method of assessing the outcome of any form of treatment. The results of incomplete retrospective studies may be very misleading when used in the assessment of clinical management or the future planning of services.

In the present state of our knowledge it is unlikely that the outcome of treatment, which is influenced by a great many variable factors, can be significantly affected by the manipulation of one of them. Much attention has been given in recent publications to modifications of treatment régimes designed to reduce the incidence of later complications. None of these has met with sufficient success to obviate the need for long-term follow-up. Thyrotoxicosis can be effectively treated by the currently available empirical methods; if hypothyroidism is an inevitable consequence of this it should be diagnosed early and treated adequately. Emphasis in the past on the active and early stages of treatment has resulted in a high level of undetected iatrogenic disease.

WHY FOLLOW-UP HAS FAILED

The development of a solution to the problem of long-term aftercare for these patients was preceded by an appraisal of the parts of the health service responsible for the patients' care and an examination of the reasons why follow-up has failed in the past.

In a study of post-thyroidectomy patients in North-east Scotland (Hedley, Flemming, Chesters, Michie, and Crooks, 1970) no difference could be found between patients recalled by the follow-up survey itself and those on the survey list who were referred specifically by their general practitioner. This suggests that many patients' use of the medical services is random and not related simply to the presence of symptoms or their severity but also to other factors.

Table II.—Long-term Results of Subtotal Thyroidectomy

Author	Maximum Follow-up Period (yr)	Percentage of Patients who were Hypothyroid	Percentage of Patients with Recurrence	Total Morbidity
Crile and McCullagh (1951)	10	4·5 21·0	15·0 2·1	19·5 23·1
Green and Wilson (1964)	14	5·0	8·0	13·0
Nofal and others (1964)	16	28·0	—	>28·0
Roy and others (1967)	9	5·0	11·0	16·0
McNeill and Thompson (1968)	14	6·5	12·5	19·0
Hedley, Flemming, and others (1970)	21	35·6	4·0	39·6

The Patient and the Presence of Disease.—The reasons why patients will admit to but not spontaneously complain of symptoms of considerable severity which are present for long periods are not easily defined. At least part of the problem is related to the treatment act itself, the way in which it is carried out, and the nature of the complications which occur later. In common with many other forms of definitive treatment (for example, partial gastrectomy) nothing has been done, understandably, to dissuade the patient from the view that the treatment will effect a cure. Less understandable is the fact that no account has been taken of the possible concomitant disruption of normal physiological processes and many of these complications have only been recognized long after the treatment has become established as a standard practice. As a result neither the patient nor the general practitioner has been prepared for the onset of late complications; when symptoms do occur they are frequently dissociated from the treatment act both in time and in the patient's mind. The symptoms of hypothyroidism occurring late are frequently attributed to the ageing process. The onset of recurrent hyperthyroidism may be equally as insidious and sometimes the symptoms may be mild or absent in contrast to other aspects of the metabolic disturbance. Hypothyroidism usually occurs early after subtotal thyroidectomy for thyrotoxicosis and here it is often not clear that symptoms, if they are present at all, are related to thyroid dysfunction, because they are opposite in nature to the complaint for which the patient has recently received successful treatment. In both hypothyroidism and hyperthyroidism there is often a profound disturbance of mental function, which probably occurs to a greater extent in hypothyroidism (Whybrow, 1969). The slow onset of apathy, somnolence, and listlessness may be accompanied by abnormalities of cognitive function and depression, all of which contribute to the failure of the patient to rationalize the situation and seek medical advice.

In retrospective follow-up studies, failure to find more than 50 per cent of the population 'at risk' can easily be ascribed to the behaviour or idiosyncrasies of individual patients. Untraced patients can be shown to have migrated, emigrated, joined an organization which obliges them to move about (e.g., military forces), changed their name (e.g., marriage), or encountered other problems such as separation, divorce, prison, and debilitating physical or mental illness, all of which complicate their follow-up or modify their responses to recall which takes place some considerable time after the original treatment. It would be quite wrong to lay the responsibility for this failure in communication solely on the patient, particularly as it can be clearly shown that the machinery for either retrospective or prospective follow-up is not provided within the framework of the existing health services.

Medical Records.—One major defect has been in the organization of the medical records systems through which these patients must be identified. Retrospective studies have shown that the present methods of recording and updating basic identification information in hospital, general practice, and executive council records are wholly inadequate, and in many instances are non-existent. Furthermore, there is very little cross-communication between these information stores.

The identification data and allied information collected for the patient's record at the time of admission to hospital are not necessarily the same as those required when long-term follow-up begins. The present format of the hospital case record is often unsatisfactory for its intended purpose and altogether unsuitable as a follow-up document. With the present system of medical records, follow-up should be carried out as a separate but parallel exercise to the routine work of wards and clinics. However, the follow-up records should be complementary to those in hospital and the latter should be constantly updated with any changes in the patient's follow-up status.

The Hospital Service and the General Practitioner.—The responsibility for follow-up must either lie with the general practitioner (providing primary care) or the hospital clinic (which gave the special treatment). The sharing of responsibility for patients of mutual interest between these two parts of the health service has never been clearly defined and in addition they both face special problems.

Because of the overwhelming demand on curative medicine the hospital services are deeply committed to the treatment of new patients and have no additional resources to provide a comprehensive follow-up scheme to detect iatrogenic disease. If the hospital accepts the responsibility for aftercare for patients 'at risk' it is usurping the responsibility of the general practitioner. Furthermore, even if the number of new referrals remained constant the cumulative clinical commitment would soon reach prohibitive proportions. When patients continue to attend an out-patient department for long periods there is an implication that they are better handled in this way than by their general practitioner. This may occasionally be true, but as a routine method of patient care it can only be justified if a special skill is required throughout the long period of attendance. In fact this is infrequently the case and many patients continue to attend hospitals because the onus is on no one to discharge them.

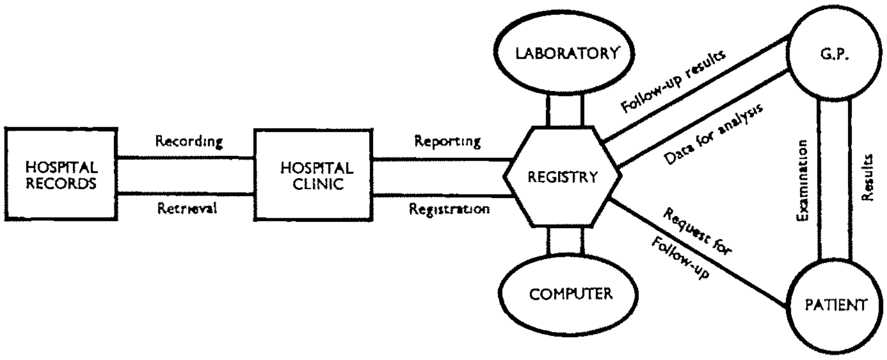

FIG. 1.—Flow diagram of the Scottish Automated Follow-up Register showing the relationship between hospital, general practitioner, patient, and registry. (*Reproduced by permission of the Editor, 'Scottish Medical Journal'.*)

The responsibility for primary care must lie with the patient's own doctor. However, general practitioners seldom have access to appropriate laboratory and data-processing facilities which would enable them to carry out the kind of follow-up which is needed. Several centres do include thyroid-function tests in the range of laboratory investigations routinely available to general practitioners, but in any one practice the patients who require the test are usually small in number and widely dispersed, which makes efficient use of the laboratory facility extremely difficult. However, many difficulties would be avoided and advantages gained if the follow-up arrangements were under the control of the family doctor; for example, within the health service our patients are automatically divided into small manageable groups within each general practice unit. The general practitioner is working in a community which is relatively static and he therefore has, or should have, greater opportunity than most doctors to practise continuity of care. The importance of the general practitioner in follow-up is also linked to the need to motivate patients to seek help; most patients usually prefer to be attended by their family doctor rather than the comparatively hostile environment of the out-patient department. At the same time care must be taken to avoid the deep involvement of the general practitioner in complicated and unproductive routine examination of his patients.

Migration and Emigration.—A feature of the age in which we live is the increasing mobility of the population, which equally applies to the population of 'at-risk' patients under study. When patients leave a district they leave their general practitioner, out-patient clinic, and often their medical records behind them (Acheson, 1967). The movement of patients is increasing at a considerable rate. For example, in the 50 years up to 1970 the population in North-east Scotland fell by almost 7 per cent whereas the population of the whole of Scotland increased by 9 per cent. The process of depopulation is particularly marked in the highlands and islands. For example, the population of Orkney and Shetland fell by 43 per cent in the hundred years before 1951 and the rate of decline is increasing, having been 6·6 per cent in the 20 years before 1951 and 10 per cent in the 10 years since then (Registrar-General, 1961; Hall and Baldwin, 1968).

Changes of this kind are not confined to patients. Doctors move and retire, or even change their interests, and their successors are not always willing or obliged to adopt the same mantle, and as a result continuity of patient care often suffers.

The Regional Geography.—Many thyroid clinics serve thinly populated rural areas. The difficulty, inconvenience, and expense (not recoverable without a means test), and often the hazards associated with travelling to central clinics, reduce the likelihood that successful contact will be maintained with patients over a long period of time. For patients in outlying districts such as the Scottish islands, attendance at a central clinic on the mainland for a check-up examination is not possible.

Conclusions.—It is clear that traditional methods of medical care are not sufficiently developed or flexible enough to overcome the kind of organizational problems which confront those responsible for patient follow-up. Provision of general practitioner facilities for investigation of thyroid function is not sufficient; unless the aftercare of small selected groups in each general practice unit can be co-ordinated and controlled, then follow-up may fail no matter how sophisticated are the scientific aids at the doctor's disposal.

THE NEW SYSTEM

A new system of aftercare for patients treated for thyrotoxicosis and spontaneous hypothyroidism has been developed through the collaborative efforts of computer scientists, administrative personnel, and doctors (in hospital and general practice) in the areas at present served by the five Scottish regional hospital boards. The system provides a screening and record-keeping service for general practitioners and effectively identifies patients with iatrogenic thyroid disease. The computer-assisted follow-up programme ensures continuity of care, automates all the procedures which do not require a decision by a doctor, and guarantees contact between general practitioner, laboratory, and patient at appropriate intervals.

The follow-up operations are controlled by a registry (*Fig.* 1) which maintains the follow-up file in the form of cumulative personal medical records for each patient using computer-assisted record-keeping techniques. These methods and the follow-up procedure have been described in detail elsewhere (Hedley, Scott, and Debenham, 1969; Hedley, Scott, Weir, and Crooks, 1970). The hospital clinician enters the euthyroid post-treatment patient on the register at the request of the general practitioner. The registry notifies the practitioner when a follow-up examination is due, processes the clinical information and blood sample which he returns, and finally reports the results in the form of a selective diagnosis. The secretarial functions of the automated registry include updating the patient's record in general practice and hospital, tracing non-responders, tabulating the reasons why patients and doctors discontinue their use of the system, and compilation of follow-up results including morbidity and mortality tables.

CONCLUSIONS

This new approach to aftercare circumvents many of the obstacles to effective follow-up. It leaves responsibility for patient care, outside hospital, with the general practitioner but provides him with a convenient and efficient method of carrying this out. Both the general practitioner and his hospital centre obtain accurate information for their medical records at regular intervals. The movement of patients and doctors is recorded, their files are constantly updated with changes of name and address, and the geographical problem of great distances between patient and specialist clinic no longer exists.

It may be claimed that the register link betwee general practice and hospital is an importar component of the efforts being made towards rational integration of these two parts of the healt service.

SHORT PAPERS

OBSERVATIONS ON THE TREATMENT OF TRAUMATIC URETHRAL INJURIES AND THE VALUE OF THE FENESTRATED URETHRAL CATHETER

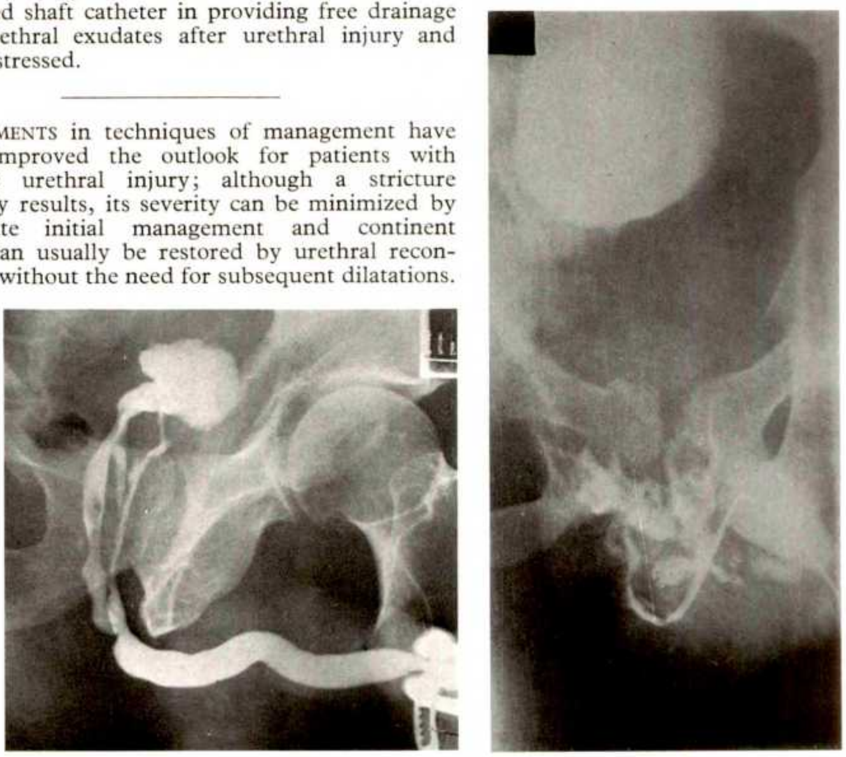
BY RICHARD TURNER-WARWICK

THE MIDDLESEX, ST. PETER'S, AND THE ROYAL NATIONAL ORTHOPAEDIC HOSPITALS, LONDON
AND THE INSTITUTE OF UROLOY

SUMMARY

A review of 250 traumatic urethral strictures in our series has provided the basis for a consideration of their management. Techniques that we have adopted or adapted for their resolution are outlined and the principles involved in reducing the effects of the initial injury are discussed. The value of the fenestrated shaft catheter in providing free drainage of periurethral exudates after urethral injury and repair is stressed.

DEVELOPMENTS in techniques of management have greatly improved the outlook for patients with traumatic urethral injury; although a stricture commonly results, its severity can be minimized by appropriate initial management and continent voiding can usually be restored by urethral reconstruction without the need for subsequent dilatations.



A B

FIG. 1.—A, Multiple false passages resulting from the treatment of a short traumatic bulbar stricture by repeated dilatation; such strictures are relatively easy to repair. B, Immediate intravenous pyelogram and synchronous retrograde urethrogram showing gross upward fracture-dislocation of the bladder and prostate with pelvic extravasation of urethrographic contrast; the 'pie in the sky' bladder.

Review of the treatment of 250 patients with strictures resulting from various types of traumatic injury has provided the basis for a consideration of the principles underlying their management and that of reducing the effects of the original injury.

PRINCIPLES OF SURGICAL REPAIR OF TRAUMATIC URETHRAL STRICTURES AND FISTULAE

Short traumatic strictures resulting from both straddle and pelvic fracture dislocation injuries are usually best treated by one-stage resection and reanastomosis (*Fig.* 1). Pedicle grafts using urothelial or skin islands provide useful one-stage techniques for slightly more extensive strictures (Turner-Warwick, 1972), but where the repair involves a trans-sphincter inlay or the surrounding tissues are grossly infected a two-stage scroto-urethral inlay is usually preferable (Turner-Warwick, 1968).

Catheter Drainage.—The larger indwelling urethral catheters (18F–22F) tend to obstruct the drainage of suture-line and rupture exudates which accumulate in the pericatheter urethral space and result in infection and fistula formation (*Fig.* 2 A); a small Gibbon catheter is an improvement since it allows some periurethral drainage (*Fig.* 2 B).

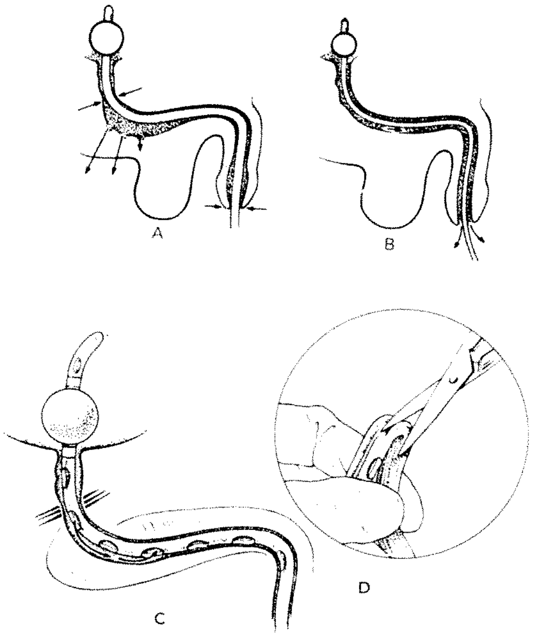


FIG. 2.—Urethral drainage and the indwelling urethral catheter. A, An indwelling urethral catheter of standard size impairs the drainage of the pericatheter space. B, Urethral drainage can occur around a small Gibbon catheter. C, A fenestrated catheter provides positive drainage and wash-out of the pericatheter space. D, Holes are easily cut in the shaft at levels appropriate to the drainage of the supramembranous and bulbar urethra; care must be taken to avoid the balloon-inflating channel. The fenestrated area of the catheter shaft must be pushed back into the bladder before any bladder wash-out is undertaken.

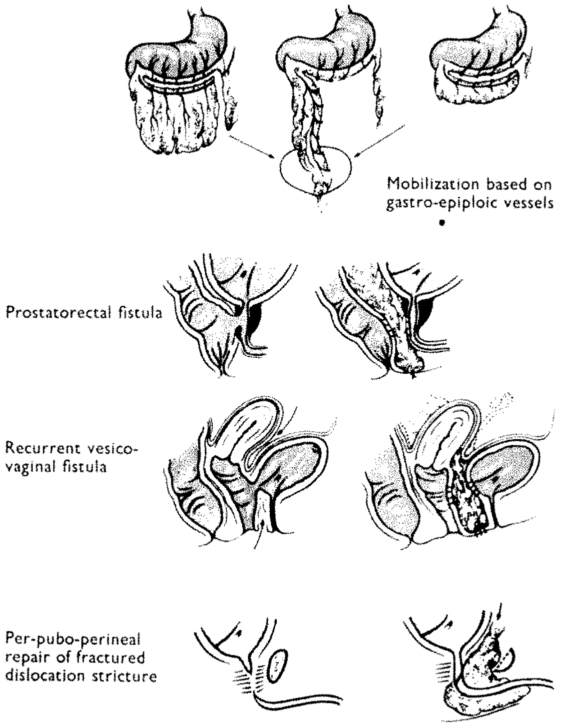
We use a specially fenestrated catheter to provide effective drainage of urethral exudates; this is particularly important in traumatic urethral injury and repair. The shaft of an appropriate catheter type and diameter is fenestrated in the area of the posterior bulbar urethra (*Fig.* 2 C); the pericatheter space is both drained and irrigated by urine, and there may be some additional siphonic suction if the catheter drainage connecting tube diameter is not too large to remain bubble free.

We routinely use this fenestrated catheter for all one-stage urethral reconstructions and for the closure of subsphincter inlay urethroplasty; in addition, it seems to provide a more effective drainage of a periurethral haematoma associated with traumatic urethral rupture than passive urethral drainage, and this is particularly important to the reduction of periurethral fibrosis which complicates subsequent urethral repair, especially in pelvic fracture injuries. We use a suprapubic catheter additionally when the bladder drainage is likely to be particularly critical or haemorrhagic. Effective bladder wash-out can only be achieved with a fenestrated catheter if it is pushed in so that all the holes lie within the bladder.

Omental Pedicle Graft.—Simple perineal bulbar and bulboprostatic anastomoses require no additional support, but the omentum is very useful for the more complex situations resulting from extensive injury and tissue loss. The omentum maintains its supple tissue consistency during and after the resolution of an inflammatory reaction and this, as well as its healing potential, makes an excellent flexible support for a bulboprostatic anastomosis inlaid through a rigid fibro-osseous tunnel, preventing it from becoming densely adherent to the wall and so risking both infection and re-stenosis.



Mobilization based on gastro-epiploic vessels
Prostatorectal fistula
Recurrent vesico-vaginal fistula
Per-pubo-perineal repair of fractured dislocation stricture

FIG. 3.—The omental pedicle interposition graft is important to the resolution of many complex traumatic injuries. Formal mobilization based on the right gastro-epiploic vessels is usually required to enable it to reach the pelvis.

Only the lower fringe of the omentum will normally reach the pelvic cavity and definitive mobilization is usually necessary for its effective use in relation to the urethra (*Fig.* 3). The application of the omental interposition graft and the technique of its mobilization have been discussed elsewhere (Turner-Warwick, Wynne, and Handley Ashken, 1967; Turner-Warwick, 1972). It is particularly useful for rebuilding the septum in traumatic vesicovaginal and prostatorectal fistulae and for the repair of post-irradiation fistulae. Even large cloacal defects resulting from gross perineal tissue-loss injuries can be repaired with it, and less heroic replacements of the perineal tissues overlying an exposed urethra are relatively simple. It is important to anticipate the possibility that it may be necessary to use the omentum in a particular case, since a long median incision is required in order to mobilize the right gastro-epiploic arch from the stomach to the splenic pedicle.

CLOSED PERINEAL INJURIES

Closed urethral damage commonly results from fall-astride or straddle injuries, the bulbar urethra being crushed against the inferior margin of the pubis. A urethral stricture commonly develops and this is usually short and relatively easy to repair by one-stage reanastomosis (*Fig.* 4) (Turner-Warwick, 1974).

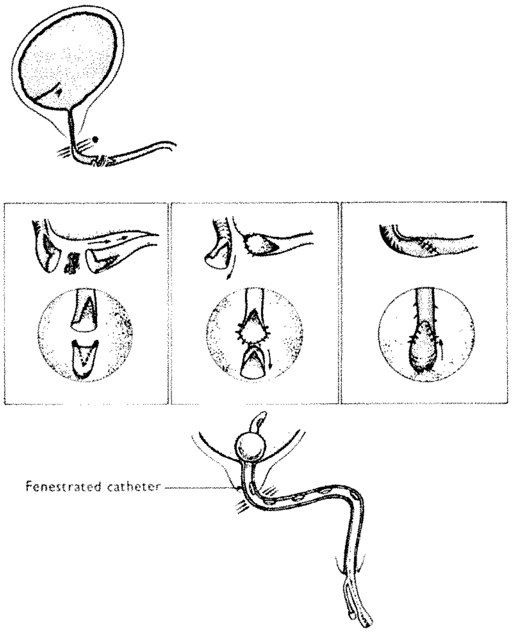


FIG. 4.—One-stage excision and reanastomosis of short bulbar urethral strictures following straddle injury; fenestrated catheter drainage. An antero-posterior overlap anastomosis reduces the risk of suture line cross-adhesion if its sides are spread apart and fixed laterally.

It is essentially the aetiology of a radiologically 'short' stricture which determines whether it should be treated by a reanastomotic or an inlay procedure. Mechanical trauma usually causes urethral scarring localized to the injury and the results of overlap reanastomosis are consequently good (*Fig.* 5).

The relatively poor reputation of resection and reanastomosis is the result of using it for apparently 'short' bulbar strictures due to urethritis; in these the damage caused by the original infection is characteristically much more extensive than the apparent stricture length on the urethrogram suggests and, because the urethra proximal and distal to it is abnormal, reanastomosis carries a high re-stricture rate.

Scarring resulting from traumatic bulbar urethral injury naturally compromises its mobilizable elasticity so that the length of stricture that can be easily resolved by an excision and overlap anastomosis is only about 1 cm. (*Fig.* 6). If the stricture much exceeds this length only a roof-to-roof approximation is possible and the anastomosis must be completed with an island skin-patch graft or a two-stage scroto-urethral inlay (Turner-Warwick, 1968, 1972).

Anastomotic Technique.—No special instruments are necessary for the reanastomosis of a mid-bulbar stricture. We prefer 0000 or 00000 atraumatic polyglycolic acid (Dexon) to catgut sutures for this with the knots lying in the lumen. A ring retractor with stay-suture knobs is generally helpful.

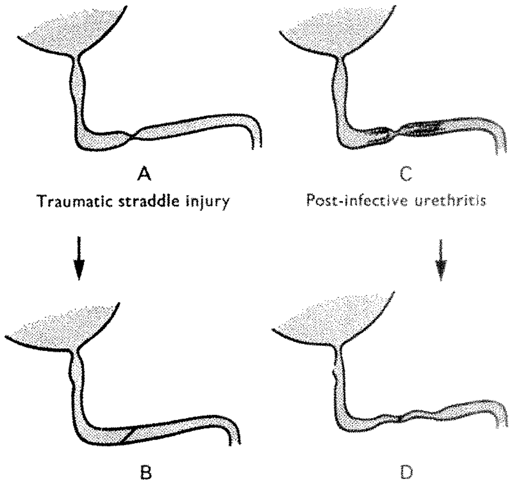

FIG. 5.—The urethra proximal and distal to a short traumatic stricture is usually normal (A) and the results of excision and reanastomosis are good (B). The urethra proximal and distal to an apparently short stricture resulting from urethritis is scarred (C) and reanastomosis results in recurrent stricture (D).

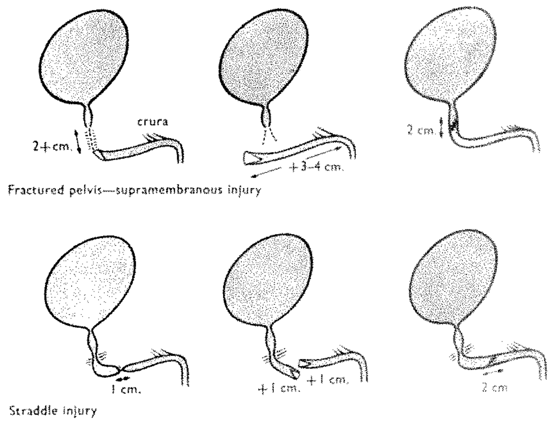

FIG. 6.—Bulbar urethral mobilization in relation to one-stage repair of traumatic bulbar and supramembranous urethral strictures.

THE IMMEDIATE MANAGEMENT OF CLOSED TRAUMATIC INJURIES OF THE BULBAR URETHRA

Urethral injury is usually indicated clinically by the appearance of blood at the meatus in association with a perineal haematoma or pelvic fracture. Depending upon the management envisaged it may be of importance not only to confirm the presence of a urethral injury but also to verify whether it is bulbar or supramembranous.

Diagnostic Radiography.—Retrograde urethrography will indicate the presence and the location of a urethral rupture but not usually whether it is complete or incomplete. Contrast media are, however, tissue irritants and excessive extravasation increases the local tissue damage. We have seen extensive tissue necrosis as a result of gross extravasation of viscid-based and also concentrated aqueous media, but this can be obviated by using a dilute aqueous solution and reducing the extent of the diagnostic extravasation to a minimum, either by limiting the volume of the retrograde injection or, better, by screening control.

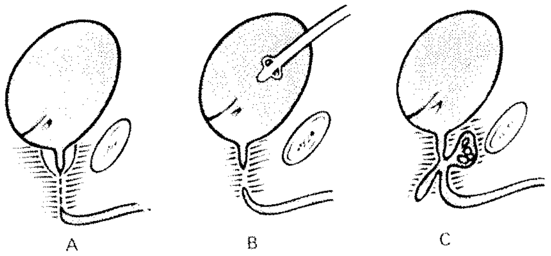

FIG. 7.—Severe fracture-dislocation in injuries may result in: (A) long strictures surrounded by dense haematoma-fibrosis; (B) complete loss of urethral continuity; (C) retropubic extravasation diverticula or fistulae which commonly contain calculi.

Urethral Catheterization.—Trial catheterization will indicate whether a rupture is partial or complete, but rough and inexpert attempts under less than ideal circumstances are rightly deprecated since it risks completion of a partial rupture and the introduction of infection. Of equal concern is that non-fenestrated catheters, once passed, are often left indwelling for a period of urinary drainage; this partially obstructs the urethral drainage of exudates from the periurethral trauma and may indeed risk extension of the effects of injury as a result of haematoma retention and infection. This risk is only partially reduced by the use of a fine (10F–14F) catheter (*Fig.* 2 B).

At the present time suprapubic catheter drainage of urine is the most generally accepted procedure for the immediate treatment of closed bulbar urethral injuries and any alternative must be carefully measured against this procedure, for the results are good and the subsequent repair of any bulbar stricture that occurs is relatively simple. Exudates can drain passively down the urethra, and while it is possible that this could be improved by positive fenestrated catheter drainage the advantages of avoiding further urethral damage by inexpert attempts at catheterization are generally overriding.

A total bulbar rupture almost inevitably results in the development of a stricture if it is treated by simple suprapubic catheterization. The immediate exploration and repair of the more severe closed bulbar injuries may have some advantages over suprapubic catheter drainage and delayed repair but is only advisable for specialist management. It is notoriously difficult to determine the limits of tissue viability in contused tissue and a recurrent stricture after a failed one-stage reanastomosis is more difficult to repair than one resulting from conservative treatment; an immediate roof-to-roof bulbar anastomosis with a scroto-urethral inlay, however, provides an equally satisfactory end result and may be more convenient than the alternative interim period of suprapubic catheter drainage. Marburger (1969) has a particular experience of immediate urethral exploration after tree-straddling ski-ing injuries.

URETHRAL INJURIES ASSOCIATED WITH PELVIC FRACTURE-DISLOCATION

The extent of the initial prostatic dislocation may be considered as minimal, moderate, or severe. A minimal supramembranous rupture usually compromises the intrinsic mechanism of the distal sphincter (the isolated loss of this may pass unnoticed, though it may later result in incontinence after prostatectomy); a short supramembranous stricture commonly develops but its appearance is sometimes delayed (Turner-Warwick, Arnold, and others, 1973).

A periurethral haematoma commonly accumulates in the floor of the pelvis at the apex of the prostate in patients with even a minimal fracture-dislocation; it is the organization of this that leads to the characteristic dense supramembranous periurethral fibrosis. The healing process in such a case may result in a further important complication which may compromise a simple perineal approach to the later repair. Urinary extravasation into a cavitating apical haematoma may create a urethral extravasation diverticulum or fistula and this may ultimately persist as an epithelized cavity or fistula in the dense fibrous tissue and calculi often form within it (*Fig.* 7).

Upward dislocation of the prostate results in a proportionally longer stricture through the dense fibrosis and sometimes a total loss of continuity if the false trans-passage is not maintained by dilatation. Distraction neuropathy resulting from dislocation may cause permanent impairment of potency and bladder dysfunction which compromises the bladder-neck–detrusor mechanism of urinary control (*Fig.* 10).

Reconstruction of Urethral Continuity.—We usually prefer to treat the established short supramembranous traumatic stricture by direct suture of the spatulated proximal end of the mobilized bulbar urethra to the prostatic urethra (*Fig.* 8) rather than by the indirect Solovow-Badenoch 'pull-through' procedure. Special instruments are helpful for high bulboprostatic anastomosis, in particular the fibrelight posterior urethral retractor and the three curves of posterior urethral needle for inserting 000 supramembranous Dexon sutures (Turner-Warwick, 1974).

Stricture Length in relation to Urethral Reanastomosis.—If the bulbar urethra is detached proximally at the level of the membranous urethra and mobilized to the penoscrotal junction it can be elongated some 3–4 cm. in the adult without undue tension. An oblique urethral suture line with about a 2-cm. overlap is advisable in order to avoid anastomotic narrowing, because the urethra is particularly prone to re-stenosis as a result of cross-adhesions of suture-line granulations. It follows that the length of a supramembranous stricture that can readily be resolved by direct bulboprostatic anastomosis without penile shortening or additional mobilization is in the region of 2–3 cm. Longer strictures can be resolved by approximating the penoscrotal junction to the apex of the prostate by mobilizing the suspensory attachment of the penis or resecting the pubis.

Synchronous Per-puboperineal Urethroplasty.—For the longer strictures and those associated with extensive fibro-osseous occlusion or extravasation diverticula we have used a synchronous approach from above and below (*Fig.* 9). The additional use of the omentum seems important to protect the urethroprostatic anastomosis if it lies in a fibro-osseous tunnel and also any exposed bone. A partial resection of the back of the pubis (*Fig.* 9) may obviate the need for a total pubic resection and this is technically facilitated by a Capener's bone gouge. The overall results of this combined approach with additional omental support have been remarkably good (Turner-Warwick, 1974).

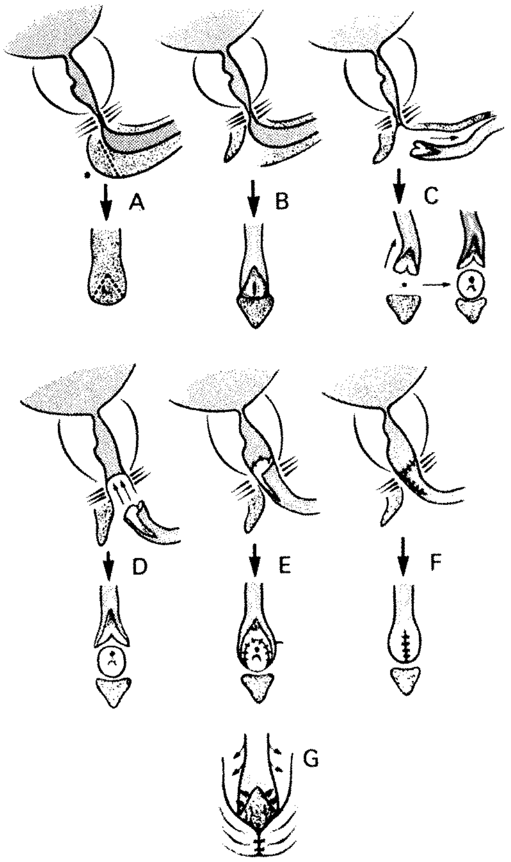

FIG. 8.—One-stage push-in bulboprostatic anastomosis. A, The posterior bulbar cavernous tissue lies behind the urethra. B, It is reflected as a posterior flap to facilitate subsequent closure; excess cavernous tissue at the anastomosis causes periurethral fibrosis. C, D, The bulbar urethra is mobilized to the penoscrotal junction and the stricture scarring excised to allow free passage of a finger to the prostatic urethra. E, F, The urethroprostatic sutures are inserted with posterior urethral needles using 000 absorbable sutures and fenestrated catheter drainage. G, Over-closure of the posterior cavernous tissue flap and additional lateral sutures are placed to 'push' the bulbar urethra towards the anastomosis and prevent tension due to erection.

Sphincter Function after Urethral Injury.—The restoration of urethral continuity often presents a formidable surgical problem but, assuming that it can be achieved, the functional result is dependent upon the survival of the bladder-neck sphincter mechanism because the composite distal sphincter mechanism (previously referred to as the 'external sphincter') is commonly ablated by the initial pubic arch injury (*Fig.* 10). An understanding of the elements of urinary control is important to the management of this type of stricture. In order to be continent of urine at rest the patient normally requires either an efficient bladder-neck mechanism or an efficient intrinsic mechanism of the distal group of muscles; the extrinsic muscles appear virtually incapable of maintaining resting urinary continence. The normal patient can interrupt his voiding stream by momentary contraction of the extrinsic muscles, the intrinsic mechanism then empties the proximal posterior urethra retrogradely, and the bladder neck closes as a result of detrusor inhibition (Caine and Edwards, 1958; Turner-Warwick, Whiteside, Worth, Milroy, and Bates, 1973) (*Fig.* 10 E).

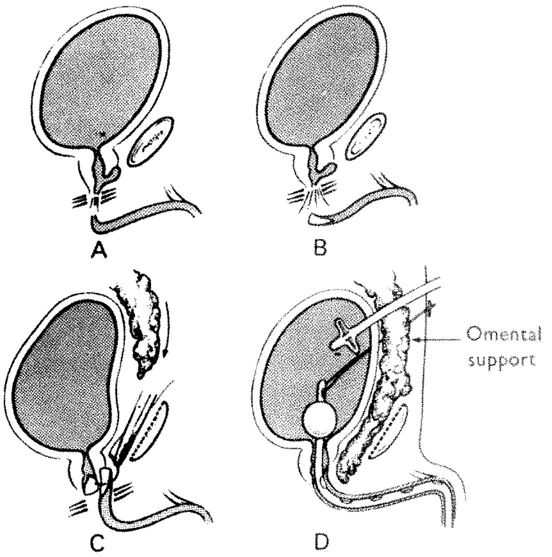

FIG. 9.—Synchronous per-puboperineal repair of traumatic urethral stricture. A, The bulbar urethra is mobilized in the perineum. B, The retropubic space is explored through a midline incision which can be extended upwards for omental mobilization. Access to the front of the prostate is facilitated by resection of the posterior part of the pubis. C, The mobilized bulbar urethra is passed up through a tunnel created in the fibro-osseous pelvic floor and sutured to the anteriorly opened prostatic urethra under direct vision from above using 000 absorbable sutures on conventional atraumatic needles. D, The tunnelled urethra and anastomosis are protected by a mobilized omental wrap. The bladder is drained by fenestrated urethral and suprapubic catheters.

A patient who is totally lacking in the elements of the distal urethral mechanism may nevertheless be continent on the basis of his detrusor–bladder-neck mechanism, for although he is unable to interrupt his voiding stream suddenly in the absence of the extrinsic urethral sphincter, he can interrupt it slowly as part of the voluntary inhibition of the detrusor contraction which results in the bladder-neck closure (*Fig.* 10 F).

It follows that preservation of the bladder-neck sphincter is vital to the functional result of supramembranous urethroplasty and every effort must be made to avoid impairing this both during the initial treatment and in the resolution of any subsequent stricture.

It is also of great importance to appreciate that global bladder hypertrophy is a natural result of outflow obstruction due to a long-standing urethral stricture; erroneous bladder-neck ablation based on the mistaken impression that the endoscopic appearances of trabeculation and bladder-neck hypertrophy represent dysynergic bladder-neck obstruction is an all too common surgical disaster that may compromise a successful functional result of a stricture repair (Turner-Warwick, Whiteside, and others, 1973).

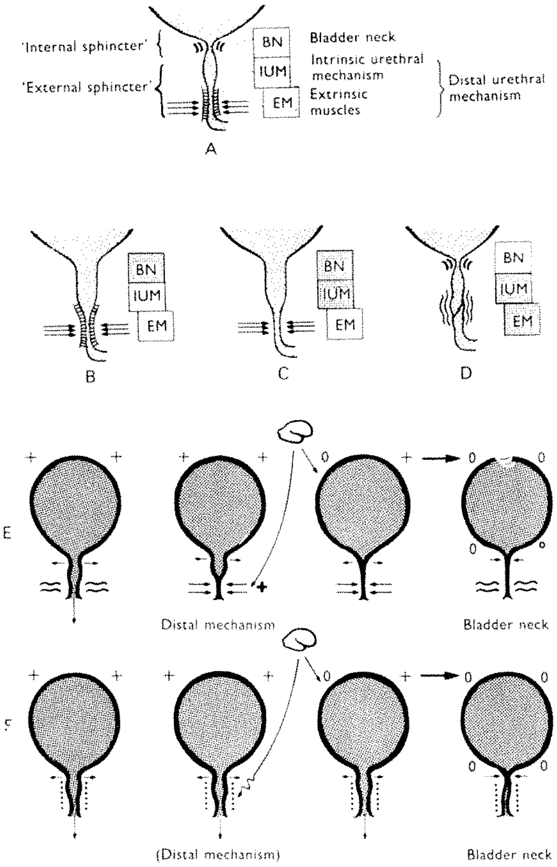

FIG. 10.—Isolated sphincter mechanisms after surgical procedures in the male, and the interruption of the voiding stream. A, Normal sphincter mechanisms. B, Continent after prostatectomy. C, Incontinent after prostatectomy. D, Urethroplasty for supramembranous stricture after fractured pelvis; continence dependent on detrusor–bladder-neck inhibition. E, Normally the mid-voiding stream can be voluntarily interrupted by the extrinsic distal sphincter with retrograde emptying of the urethra by the intrinsic distal mechanism and bladder-neck closure after detrusor inhibition. F, Loss of the distal mechanism. The mid-voiding stream can only be interrupted slowly by voluntary inhibition of the residual detrusor–bladder-neck opening mechanism.

THE IMMEDIATE MANAGEMENT OF FRACTURE-DISLOCATION INJURIES

The immediate concern in patients with fracture-dislocation is to preserve life; many are critically ill at the time of admission and the urological problem may be relatively low on the list of immediate priorities.

The whole of the urinary tract is at risk in such injuries; the urethra is damaged in a minority of cases and gross upward dislocation of the prostate occurs only in a few patients. The bladder may be additionally damaged.

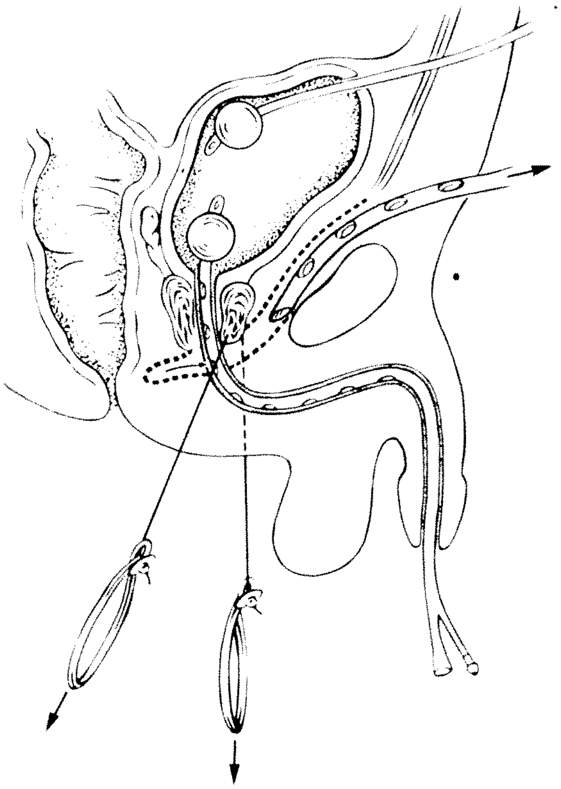

FIG. 11.—Operative treatment of fracture-dislocation of the prostate: Retropubic evacuation of haematoma; fenestrated urethral catheter for urethral alinement and apical drainage, additionally retained by suprapubic suspension stitch; elastic-band traction on apical prostatoperineal sling suture to maintain prostatic reduction; additional suprapubic catheter and retropubic suction drainage.

The initial problem is one of diagnosis. *Immediate intravenous pyelography* (I.I.V.P.) is of special value; not only may it exclude concomitant upper-tract complications but the position of the bladder shadow is often helpful in that it may be seen to be normally low lying, laterally compressed by the pelvic haematoma, or overtly dislocated upwards. A controlled dilute aqueous retrograde urethrogram will confirm or exclude a significant urethral injury but not its extent.

A high-riding dislocation of the prostate is relatively rare. It is, however, of great importance that this situation should not be missed, for it results in a formidable stricture problem if it remains unreduced. The diagnosis may be suspected by the absence of a normally placed prostate on rectal examination, although this may be difficult to determine as a result of the haematoma; the bladder shadow on the I.I.V.P. may show gross dislocation (*Fig.* 1), but a low-lying bladder does not exclude a significant distraction injury.

Treatment.—Treatment of patients with gross prostatic dislocation by simple suprapubic catheterization without drainage tends to result in a massive haematoma-fibrosis and a formidable stricture; even if the haematoma is evacuated as far as possible and drained retropubically a disproportionate apical periurethral fibrosis seems to result all too frequently.

The technique of maintaining the reduction of a prostatic dislocation by traction on a balloon catheter should probably be abandoned, for not only does an unfenestrated catheter shaft prevent the urethral drainage of the apical haematoma even when combined with a retropubic drainage but also it must carry an additional risk of injury to a surviving bladder-neck mechanism as a result of traction pressure (*Fig.* 10 D).

Primary prostato-urethral anastomosis through a retropubic approach is technically difficult and it is often virtually impossible to achieve a reliable sutured approximation of the prostatic apex to the shattered remnants of the pelvic floor. A transpubic resection and definitive reanastomosis offer a surgeon with proper experience of the technique a more rational approach for selected cases.

At the present time we would advocate a retropubic exploration of patients with a large pelvic haematoma, evacuating it and inserting a fenestrated 18F–20F Foley catheter through the urethra and into the bladder but only to provide urethral alinement and positive drainage of the apical haematoma (*Fig.* 11). (Accidental premature removal of this is prevented by a suprapubic retaining suture.) Any traction that may be required for the reposition of the prostate is applied to the apex of the prostate with a sling suture passed through the anterior commissure, each end being passed out into the perineum, lateral to the urethra, and each with a button stop and elastic band anchorage to the respective thigh. A retropubic suction drain and an additional suprapubic catheter are inserted to ensure efficient bladder drainage. A sling suture is a relatively simple procedure and may be helpful in reducing an apical urethral rupture completely even if the prostate is not much dislocated.

When the prostate is not dislocated a suprapubic catheter will provide effective bladder drainage, but even with additional retropubic drainage it does not always seem to resolve the apical haematoma effectively and the subsequent organization of this is largely responsible for the final periurethral fibrosis that commonly results. A simple indwelling urethral catheter makes the situation worse by obstructing the passive urethral drainage of exudates. The fenestrated catheter provides positive drainage to the periurethral space in this type of rupture and we hope that it will prove to reduce the extent of apical haematoma fibrosis.

It would also seem reasonable to use a fenestrated catheter for the management of a partial supramembranous urethral rupture when it can be passed into the bladder without difficulty, but free catheter drainage must of course be ensured. It is important to check that the catheter has in fact entered the bladder; a cystogram will confirm this and also exclude a concomitant bladder injury (the fenestrated shaft must be pushed fully into the bladder before contrast injection in order to avoid extravasation).

Traumatic urethral injury and extravasation of urine are major complications but do not require the most urgent immediate treatment; specialist management is indicated and premature attempts at trial catheterization in the admission room are generally inexcusable.

INTERNAL URETHRAL TRAUMA IN THE MALE

Only the occasional meatal stricture resulting from an indwelling catheter fails to respond to intermittent dilatation and subsequently requires a meatoplasty. Strictures in the membranous urethra following transurethral or open prostatectomy are usually better treated by dilatation since the bladder neck was ablated by the initial procedure and the apical damage which created the subsequent stricture usually impairs the intrinsic urethral mechanism and a transmembranous urethroplasty therefore carries a risk of incontinence. The characteristic strictures in the mid-anterior urethra resulting from instrumentation in children and adolescents present a relatively simple inlay repair problem (Turner-Warwick, 1968, 1974).

TRAUMATIC INJURY IN THE FEMALE

Traumatic injuries of the female urethra most commonly occur as a result of obstetric or gynaecological complications, and repair does not usually present a very difficult surgical problem (Turner-Warwick, 1970), but the functional result is of course dependent upon the survival of the sphincter mechanism.

Since females have in fact only a posterior urethra and both it and the pelvic floor are relatively elastic it is unusual for the urethra to be damaged in association with pelvic fractures although bladder injuries are not uncommon.

Acknowledgements.—I am most grateful to the many colleagues who have referred these interesting problems and to Miss Freda Wadsworth of the Institute of Urology for most helpful illustrations.

THE OUTCOME OF TREATMENT AND CHANGES IN PRESENTATION OF PRIMARY HYPERPARATHYROIDISM

BY D. C. BRITTON, I. D. A. JOHNSTON, M. H. THOMPSON, AND L. B. FLEMING
DEPARTMENT OF SURGERY, UNIVERSITY OF NEWCASTLE UPON TYNE

SUMMARY

A review of 105 patients operated on over a 25-year period for primary hyperparathyroidism indicates that the diagnosis is now being made at an earlier stage of the disease. The incidence of bone disease is falling but renal symptoms remain the principal reason for presentation.

Hypertension in the presence of established disease persists after successful surgery and renal function frequently continues to deteriorate. Renal function is little affected in patients with minimal symptoms.

An accurate diagnosis can be made on the basis of persistent hypercalcaemia and elevated serum parathormone levels in peripheral or neck venous blood measured by sensitive immuno-assay.

Surgery is indicated as soon as the diagnosis is established with certainty even in the absence of any symptoms.

THE diagnosis of primary hyperparathyroidism is being made earlier in the course of the disease and neck exploration is often undertaken in patients with very few symptoms.

The management of patients with hypercalcaemia and primary hyperparathyroidism but with no symptoms is problematic. There is some doubt as to whether the neck should be explored at once on the basis of the biochemical evidence or else delayed until the onset of symptoms.

The answer to this question must be based in part on the results of surgery in patients with symptoms whose serum-calcium levels return permanently to normal after operation.

The mode of presentation and the outcome of surgery were examined in 105 consecutive patients with primary hyperparathyroidism treated in one unit during a 25-year period. Renal function was studied in 52 patients 2 or more years after successful parathyroid surgery.

RESULTS OF TREATMENT

Neck exploration was carried out in 105 patients with hypercalcaemia when the diagnosis of primary hyperparathyroidism was established. Eighty-two patients were female and 23 were male. Their ages ranged from 16 to 80 years but the majority of the patients were middle-aged females. Abnormal parathyroid tissue was removed at the first operation in 96 cases, with an immediate return of the serum-calcium levels to normal. A second operation was required in 4 patients before the calcium levels fell to normal. No abnormal parathyroid tissue was found in the remaining 5 cases and in 3 of these the serum calcium returned to normal. It is reasonable to suggest that the diagnosis was wrong in these patients. Hypercalcaemia persists in 2 patients and further exploration is planned for 1 of these. Treatment was thus successful in restoring the serum calcium to normal in 96 per cent of the patients.

Eighteen patients were found to have died at the time of the review. Eight patients had died from conditions unrelated to parathyroid disease but the rest had died from causes which could be related directly or indirectly to the complications of primary hyperparathyroidism. Four patients who all had hypertension before operation died from complications of hypertension. Three patients who had impaired renal function before surgery died subsequently of chronic renal failure. Two patients died in the immediate postoperative period in the early years of the series. Both had marked hypocalcaemia at the time of death which was probably related to gross metabolic imbalance. One patient died from a pulmonary embolus after a nephrolithotomy carried out shortly after a successful parathyroidectomy.

Fifty-two patients who had had an operation 2 or more years previously were examined in the review study. The most significant finding was that only 20 patients had no complaints when seen. Thirty-two patients had persistent urinary symptoms, ranging from mild dysuria to nocturia and recurrent ureteric colic. In 10 patients operations on the renal tract had been necessary following excision of parathyroid tumours. Intermittent symptoms of hypoparathyroidism were troublesome in 6 patients in this group.

Thirty-six of the 52 patients had repeated blood-pressure recordings above the normal range for their age and sex and 20 were on regular anti-hypertensive therapy (*Fig.* 1). Seventeen patients had become hypertensive since their neck exploration but the remainder were hypertensive when the diagnosis of parathyroid disease was made.

Fourteen patients had blood-urea levels elevated above 40 mg. per cent. In 9 of them the raised level had developed since the neck exploration.

The normal range of serum creatinine was taken to be 1·0–1·5 mg. per 100 ml. Eight patients had abnormally high levels and in 5 of these the increase had occurred since neck exploration.

Eight patients had a creatinine clearance of less than 80 ml. per minute at the time of review and 4 of these patients were being treated for chronic renal failure. It was not possible to estimate the extent of the deterioration in creatinine clearance.

Intravenous pyelograms were performed in all the patients at the review and changes were detected when comparisons were made with the preoperative pictures.

The incidence of hypertension, raised blood-urea, elevated serum creatinine, and abnormal creatinine

"Intravenous feeding of a fat-free preparation **for as short a time as 5 or 10 days** caused perceptible depletion of reserves of essential fatty acids. ....One case, maintained on fat-free intravenous feeding for 4.5 months, developed severe dermal lesions and the ratio of 20:3/20:4 in serum phospholipids reached 18, **the most extreme value thus far observed in animals or man.** Tissues from this case obtained at autopsy revealed the same abnormal pattern of fatty acids in triglycerides and phospholipids as was found in the serum lipids, confirming the extreme EFA deficiency." (American Journal of Clinical Nutrition (1972) Vol. 25 pp. 897–904).

Although it may be possible, but not necessarily desirable when feeding patients intravenously, to meet energy requirements entirely by way of hypertonic sugar solutions, these solutions do not, and cannot, supply essential fatty acids. The intravenous fat emulsion Intralipid will, on the other hand, supply not only the essential fatty acids but also a large amount of energy in a relatively small volume of isotonic fluid.

Vein problems too are reduced to an absolute minimum.

Amino-acids, carbohydrate and fat – the essential ingredients of a balanced diet – from the Vitrum range of intravenous nutrients.

Aminosol 10%, Aminosol-Glucose, Aminosol-Fructose-Ethanol, Vamin, Intralipid 10%, Intralipid 20%.

clearance was significantly less in the patients seen in the last 2 years compared with the first 20 years of the series.

The restoration of serum-calcium levels to normal is thus not the most important indication of a successful result of treatment. The persistence of symptoms and the decline of renal function are not related to the restoration of calcium homeostasis.

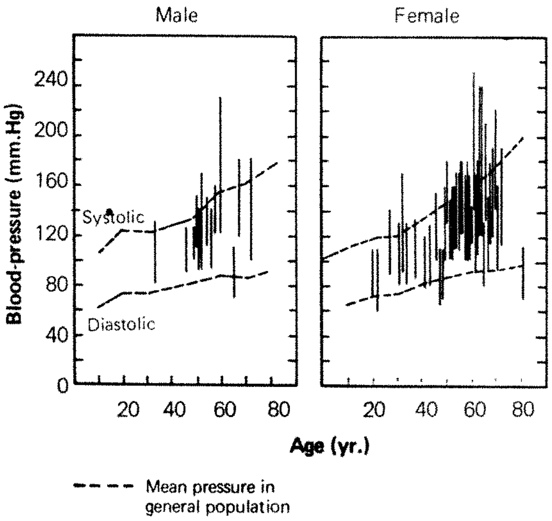

FIG. 1.—Blood-pressure in 52 patients 2 or more years after operation for primary hyperparathyroidism compared with the mean pressure in the general population. (*Reproduced from Britton, D. C., and others (1971), 'Lancet',* **2**, 74.)

PRESENTATION

The pattern of presentation during the past 25 years has changed significantly (*Fig.* 2). During the first 10 years all the patients were referred because of skeletal complications. In the second decade only 10 per cent were referred with bone disease and 80 per cent had urinary problems. The remaining 10 per cent had a mixture of symptoms including muscle weakness, dyspepsia, and mild dementia.

Forty-seven patients have been referred in the past 5 years, which is almost as many as were seen in the previous decade. The pattern of presentation has continued to change. The majority still have urinary symptoms (*Fig.* 2) but there has been a threefold increase in the number of patients with non-specific complaints. Nine of this group were totally asymptomatic, 4 were discovered as a result of the development of neonatal tetany in their newborn infants, and 5 were found as a result of random calcium estimations during investigation for unrelated complaints. Three patients were found to be hypercalcaemic in a survey of 500 patients 15 years after surgery for duodenal ulcer.

Preoperatively, 3 of the patients with non-specific complaints had slightly raised blood-urea levels, which have persisted at follow-up, but none of them has yet shown any sign of progressive renal dysfunction. Raised blood-urea levels fell to normal in 9 patients in the non-specific group and no patient in this group had a high serum-creatinine value.

CONFIRMING THE DIAGNOSIS

The biochemical diagnosis is becoming more and more important as the presenting symptoms are related less easily to the parathyroid glands.

The development of a sensitive radio-immunoassay of serum parathormone has been of value in the management of the last 14 cases in the present series.

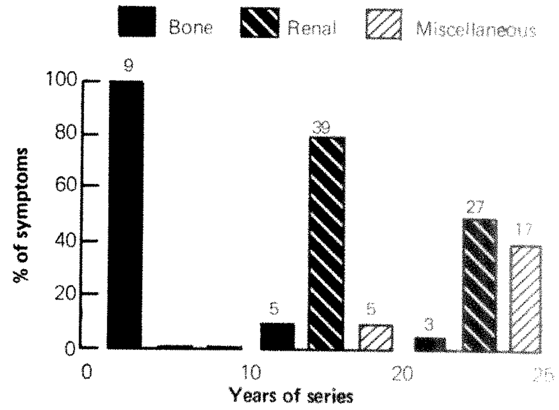

FIG. 2.—The changing pattern of presentation of primary hyperparathyroidism during 25 years.

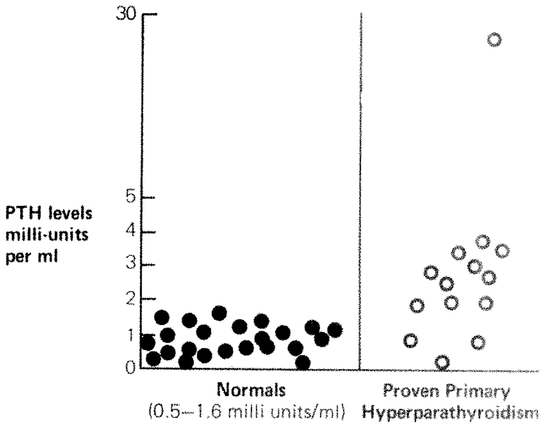

FIG. 3.—Serum-parathormone levels in primary hyperparathyroidism.

High peripheral blood-parathormone levels have been found preoperatively in 11 out of 14 cases with subsequently proved primary hyperparathyroidism. In 3 patients peripheral blood-levels were within normal limits (*Fig.* 3). Preoperative localization of a parathyroid tumour can be achieved by assaying blood samples taken from the veins of the neck under radiological control. Powell and others (1972) have reported a 56 per cent success rate in preoperative tumour localization. Using this method, localization has been attempted in 6 patients in this series and in all of them high levels of parathormone were found in the superior vena cava samples, thus confirming the presence of a tumour, but precise localization could only be predicted in 3 cases. Selective venous catheterization of the neck veins is of considerable value in localizing disease in patients who have had an initial unsuccessful exploration but it may also assist in the diagnosis of equivocal cases where hormone levels in the peripheral blood are in the normal range. An example of localization of a parathyroid adenoma in the right side of the neck is shown in *Fig.* 4.

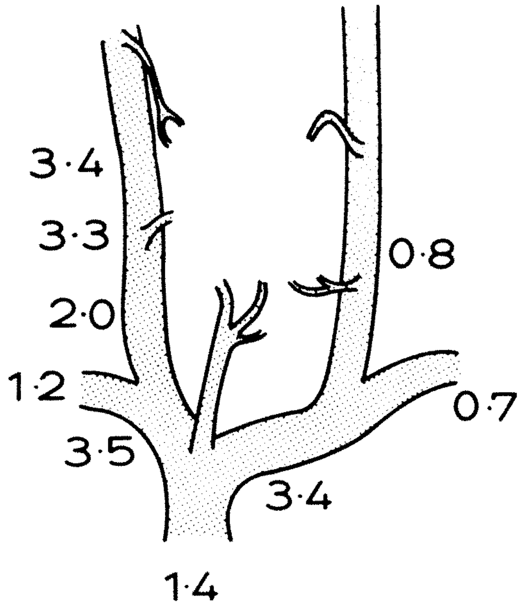

FIG. 4—Localization of a parathyroid adenoma in a patient with hypercalcaemia and few symptoms using parathormone content of selective venous samples from neck veins. (Normal PTH levels 0·5–1·6 milli-units per ml.)

Persistent hypercalcaemia is the keystone in the diagnosis of primary hyperparathyroidism in patients who are asymptomatic or who have presented atypically, but it is necessary to have some method of differentiating between hypercalcaemia due to primary hyperparathyroidism and hypercalcaemia due to other causes. The cortisone-suppression test and the selenium-methionine neck scan were used to assist in arriving at the diagnosis. The cortisone-suppression test depends upon the ability of 150 mg. of oral cortisone administered daily for 10 days to restore the serum-calcium level to normal in patients with conditions other than primary hyperparathyroidism. The hypercalcaemia of primary hyperparathyroidism is usually unaffected (Dent, 1956), but the effect of cortisone on the serum-calcium concentration in myelomatosis, secondary carcinomatosis, and the milk-alkali syndrome is inconsistent.

In practice the test has been used successfully to differentiate primary hyperparathyroidism in 23 cases. In 15 of these other stigmata of the condition had already been found, but in the other 8 successful neck exploration was carried out solely on the basis of persistent hypercalcaemia which was not suppressed by the administration of cortisone.

^{75}Se selenium-methionine neck scanning has not proved to be so reliable. It has been used in 43 patients and has localized the site of a parathyroid tumour correctly in 16 and incorrectly in 19; no localized uptake of selenium methionine was shown in the other 8 cases. The false-negative rate of 63 per cent in this series is considered to provide little assistance and this method of investigation has been abandoned.

DISCUSSION

This review indicates that more and more patients with few symptoms will be found to have evidence of primary hyperparathyroidism. Boonstra and Jackson (1971), in a survey of a general hospital adult population, found 50 patients with hypercalcaemia out of a total of 50,330 examined. This figure of 1 per 1000 examined in a hospital population has also been found by Haff, Black, and Ballinger (1970).

The management of patients found on routine biochemical screening to have hypercalcaemia and thus possible asymptomatic primary hyperparathyroidism poses a number of questions which are difficult to answer at the present time. Should surgery be carried out as soon as the biochemical abnormality is confirmed or should the patients be watched and operation delayed until symptoms develop or signs of other abnormalities can be detected? Dent (1962) has shown that some patients without bone diseases can continue for up to 40 years with hypercalcaemia before their renal function is disturbed. Purnell, Smith, Scholz, Elvesback, and Arnaud (1971) at the Mayo Clinic are engaged in a prospective study of patients with provisional hyperparathyroidism. This study may enable those patients with asymptomatic and uncomplicated hyperparathyroidism who will develop early complications to be detected and selected for surgery. It is clear that a number of patients will show the biochemical abnormality but will have no other manifestations of the disease for many years. Gough, Smith, and Bishop (1971) urge caution in exploring the neck of patients who have no symptoms or signs of disease apart from hypercalcaemia, owing to the complications associated with neck surgery.

Others, however, consider that the degree of renal impairment at surgery determines the ultimate prognosis (Britton, Thompson, Johnston, and Fleming, 1971; Chowdhury and Gray, 1973) and, because removal of parathyroid adenomas does not always cure the symptoms of the condition or allow renal function to return completely to normal, urge immediate neck exploration.

Analysis of the persistent symptomatology, renal function, and blood-pressure of the patients with classic primary hyperparathyroidism in this series who have been successfully treated shows that progressive renal deterioration and hypertension are relatively common sequelae of the disease. On this evidence it seems important to diagnose and treat primary hyperparathyroidism before renal dysfunction has developed; in effect this probably means before the classic symptoms of primary hyperparathyroidism have appeared.

There can be no clear-cut answer to the dilemma until a prospective trial of treatment has been carried out in patients with the asymptomatic form of the disease.

THE CONTINENT ILEOSTOMY

BY A. CAMERON
THE MIDDLESEX HOSPITAL, LONDON

SUMMARY

In 1969 Professor Nils Kock of Göteborg published a description of a new kind of continent ileostomy. A pouch is formed of the terminal ileum. The pouch although small at first enlarges with time until its capacity is adequate to contain about one-third of the day's ileal output. The pouch is emptied several times a day by passing a catheter along a short efferent loop of ileum which is brought to the surface as an ileostomy stoma. The pouch is made in such a way that it does not develop expulsive contractions when it fills. It is therefore continent. By constructing a valve mechanism on the efferent loop continence is maintained under the stress of increased abdominal pressure as in coughing, laughing, etc. Since the pouch is continent the patient need wear no apparatus and the ileal stoma may be made flush with the skin.

This paper describes the author's experience with 6 patients in whom this type of ileostomy has been constructed. The results confirm the claim by Professor Kock that the technique is of value in selected patients.

A METHOD of constructing a continent ileostomy has been devised and described by Professor N. G. Kock of the University of Göteborg (Kock, 1969, 1971). In this procedure the terminal ileum is fashioned into a reservoir which lies within the abdomen and communicates via a short efferent loop of ileum with a stoma on the abdominal wall. The continuous discharge from the bowel above accumulates in the reservoir, which the patient then drains intermittently by catheterization of the stoma. Between catheterizations the reservoir is continent so that no external appliances need be worn. The advantages of such an arrangement over the conventional ileostomy are apparent.

In January, 1971, the author had the opportunity of observing Professor Kock's technique at first hand. This paper gives an account of the author's experiences with the technique in 6 patients and of the results obtained.

OPERATIVE TECHNIQUE

The technique employed differs in no essential way from that now advocated by Kock. Following total colectomy the terminal 45 cm. of ileum are folded as shown in *Fig.* 1 and the adjacent limbs, each 15 cm. long, are united along their anti-mesenteric borders by a continuous seromuscular suture of chromic catgut. The bowel is then laid open (*Fig.* 1 B), taking care to extend the incision into the afferent loop for about 3 cm. Another continuous catgut suture passing through all the layers completes the first suture line (*Fig.* 2 A).

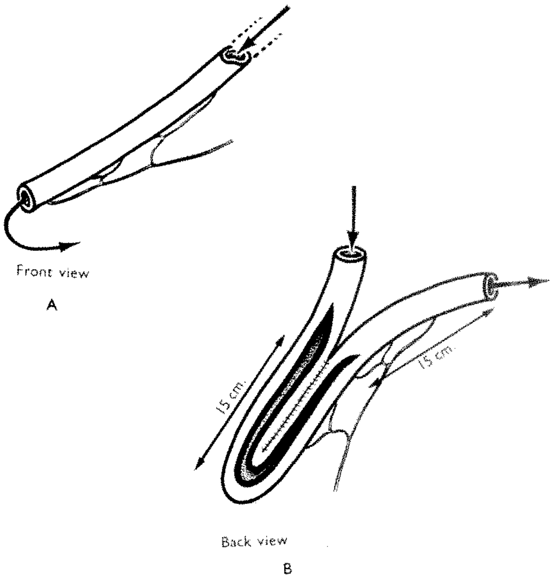

FIG. 1.—Diagram illustrating the procedure as seen by the assistant standing between the patient's legs, the patient being in the Lloyd-Davies position. In this position the assistant sees the left inferior aspect of the mesentery (A). When the bowel is folded in the direction indicated by the arrow, he then sees the right superior aspect of the mesentery (B).

A Babcock's tissue forceps is passed into the efferent loop, grasps the wall from within about 4 cm. from its junction with the reservoir, and intussuscepts it back into the reservoir. The intussusception is fixed in position by about eight black silk sutures passing through both layers of the intussusception from mucosa to mucosa. The placing of these sutures is facilitated by passing a firm plastic catheter through the efferent loop and intussusception to define the lumen. These sutures must be placed so that a nipple about 3 cm. long is fixed as a permanent projection into the reservoir. Care must be taken that these sutures do not occlude the blood-supply running in the mesentery to the efferent loop and that they effectively prevent lop-sided partial reduction of the intussusception—a complication which makes subsequent catheterization of the efferent loop impossible (*Fig.* 2 B).

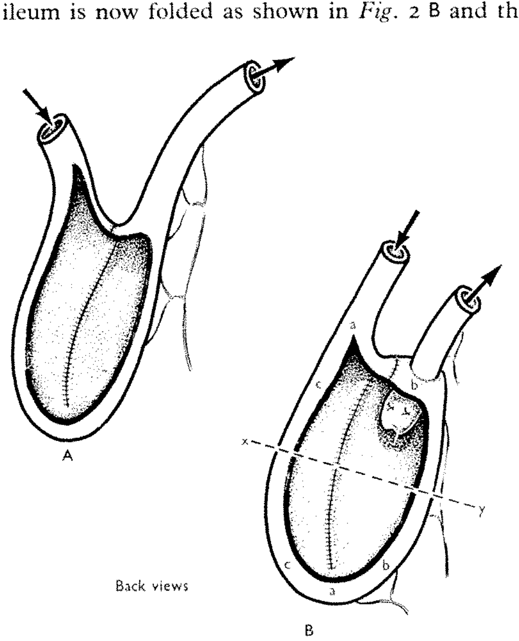

FIG. 2.—A, Both layers of the first suture line have been completed. B, The intussusception has been made and fixed with black-silk sutures. The pouch is to be folded along the line x–y so that c–c, a–a, and b–b are apposed (cf. *Fig.* 4).

The flat plate of bowel formed by the opened loops of ileum is now folded as shown in *Fig.* 2 B and the pouch is completed by continuous all-layer and seromuscular catgut stitches joining a–a, b–b, c–c, and so on. The prolongation of the original incision into the afferent loop ensures that the afferent and efferent loops are separated at their junction with the pouch by a short bridge (*Fig.* 3 A).

These steps have all been carried out from the upper right aspect of the mesentery (*Fig.* 1 B). From that aspect the pouch assumes a constricted bilobed appearance due to the pull of the mesentery (*Fig.* 3 A). If the pouch is now pushed through the mesentery and viewed from its left inferior aspect it assumes a bulbous shape which hangs snugly down towards the brim of the pelvis with the afferent loop entering it in a smooth curve and the efferent loop pointing towards the normal ileostomy site in the right iliac fossa (*Fig.* 3 B). The efferent loop is then brought through the abdominal wall at the lateral border of the rectus muscle in the usual way. Since the ileostomy is to be continent it need not project for more than 0·5 cm. or so and the opening may be made lower on the abdominal wall than usual so as to be more easily concealed.

The procedure described above is the present form of the operation and was carried out in *Cases* 5 and 6 (*Figs.* 4, 5; *Table I*). In *Cases* 3 and 4 an intussusception was made but it was not fixed with mucosal sutures and a rectus valve was made in addition. In this procedure an oblique tunnel is made through the rectus muscle and the efferent loop is brought through it so that some of the rectus fibres lie in front of the loop and some behind it. *Cases* 1 and 2 had a rectus valve made on the efferent loop but no intussusception. Since this form of rectus valve has proved less effective than the intussusception in maintaining stress continence it has now been abandoned (Kock, 1973).

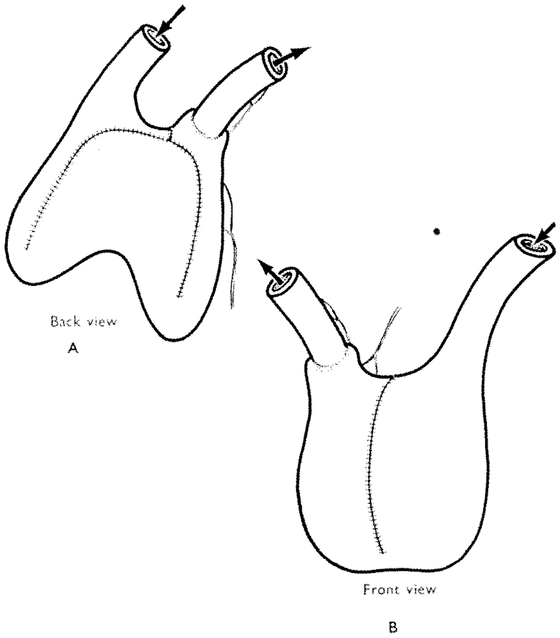

FIG. 3.—A, The completed pouch as seen from the right superior aspect of the mesentery. B, The pouch has been pushed through the mesentery and is now seen from the left inferior aspect of the mesentery (cf. *Fig.* 5).

After completion of the ileostomy but before the abdomen is closed a large-bore catheter (ileostomy catheter, AB Medena S, 434 00, Kungsbacka, Sweden) is passed into the reservoir. The afferent loop is clamped with a light occlusion clamp and the reservoir is distended with saline via the catheter to measure its initial volume (usually 50–80 ml.) and to check for anastomotic leakage. No saline should escape when the catheter is removed and light pressure is applied to the distended reservoir. Finally, the reservoir is again catheterized and drained and the catheter is fixed in a satisfactory position by means of a black-silk stitch to the skin. It is an advantage to mark the skin level on the catheter at this stage to remove doubts about its position in the postoperative period.

POSTOPERATIVE MANAGEMENT

The catheter is left in situ and allowed to drain continuously for 8–10 days. It should be washed out gently with small volumes of saline once or twice a day to prevent blockage. After this initial period it is occluded and drained 3-hourly for several days. At about 2 weeks it is removed and the pouch is catheterized 4-hourly thereafter, and as time passes the intervals can be lengthened gradually until the patient is catheterizing the pouch three or four times a day.

The stoma should be protected initially by a small square of petroleum jelly gauze.

SELECTION OF PATIENTS

The indications for operation in the 6 patients so far operated on are summarized in *Table I*.

The first patient was a woman aged 34 years suffering from polyposis coli complicated by the development of five separate carcinomas in the large bowel, one of which was in the rectum. The patient had hitherto refused colectomy because of her fear of a conventional ileostomy. Total proctocolectomy with the formation of a Kock's ileostomy was carried out as one procedure.

The third patient had had an emergency proctocolectomy with the formation of a conventional ileostomy for ulcerative colitis at the age of 78 years, 3 years previously. Her eyesight was poor owing to developing cataracts and she had rheumatoid arthritis in her hands. As a result of these disabilities she had never been able to apply the ileostomy apparatus herself. This was done by her daughter. The patient's frequent attempts to adjust the apparatus resulted in daily leakages and constant skin irritation. Prolapse of the ileostomy, which recurred after refashioning, resulted in a further decline in her well-being so that at the time of admission for conversion to a Kock ileostomy she was bedridden, incontinent, and required full-time nursing care by her daughter who had in consequence lost her job.

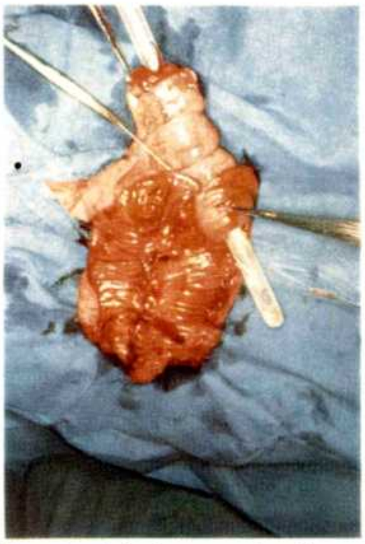

FIG. 4.—Formation of the intussusception. Photograph taken during operation showing the stage illustrated in *Fig.* 2 B.

Table I.—AGE, SEX, AND INDICATION FOR OPERATION IN THE PRESENT SERIES

CASE	AGE AND SEX	INDICATION
1	34 F.	Polyposis coli + carcinoma of rectum
2	59 F.	Ulcerative colitis
3	82 F.	Revision of conventional ileostomy
4	60 F.	Ulcerative colitis
5	65 M.	Ulcerative colitis
6	27 M.	Ulcerative colitis

In both of these patients the reservoir ileostomy offered a unique solution to a therapeutic impasse.

The remaining 4 patients were all suffering from chronic total ulcerative colitis. All 4 were in remission and were not receiving prednisone.

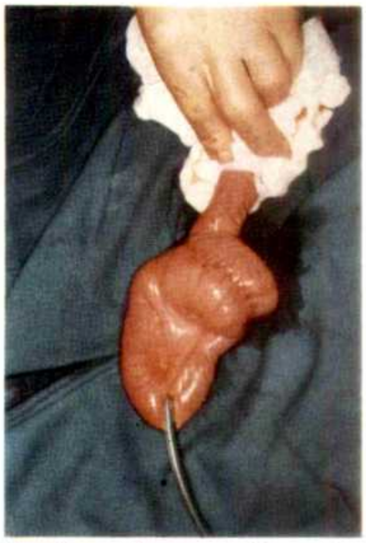

FIG. 5.—View of the completed pouch. Photograph taken during operation showing the stage illustrated in *Fig.* 3 B.

POSTOPERATIVE COMPLICATIONS

In *Cases* 1 and 3 a small abscess developed in the subcutaneous tissue close to the ileostomy about 2 weeks after operation. When this was incised and drained it was found to have a fistulous connexion with the efferent loop. In both cases the abscess healed and the fistula closed after drainage, without further treatment. Both of these cases had had a rectus valve constructed and it seemed likely that the fistula resulted from friction damage to the loop by compression between the indwelling catheter and the edge of the rectus sheath. The spontaneous healing of the fistula may perhaps be attributed to the absence of intraluminal pressure in the efferent loop and the fact that it does not usually contain faeces.

Case 6 developed abdominal distension with severe colicky pain and radiological evidence of intestinal obstruction associated with complete absence of ileostomy drainage 72 hours postoperatively. At laparotomy the small bowel was distended down to the pouch but no other abnormality was found. Twelve hours after operation the ileostomy started to drain satisfactorily. In retrospect this episode might have resolved on conservative treatment.

ASSESSMENT OF RESULTS

Clinical Assessment.—*Case* 5 died before leaving hospital from causes not connected with the ileostomy. *Case* 6 has been operated on too recently for the result to be assessed. The results in the first 4 patients are summarized in *Table II*.

Case 1, who had a rectus valve, has now had the ileostomy reservoir for 15 months. When she left hospital, 6 weeks after operation, she was passing the ileostomy catheter three times a day and was completely continent of faeces between catheterizations. The daily volume of effluent was about 300 ml. Since then the ileostomy has remained continent of faeces. As her appetite has increased with the improvement in her health she has found it necessary to pass the catheter four or five times each day. She does this when she feels that the reservoir is full, a sensation which she cannot further define. If this warning is ignored she will get transient, slight colicky pains and perhaps a slight leakage of gas from the stoma. She usually passes the catheter standing up and starts the reservoir emptying by coughing or straining. When the effluent is fluid the reservoir empties rapidly aided by pressure with the hand over the pouch, and the whole procedure is over in 5 minutes. When the effluent is thicker she washes the reservoir out with 50–100 ml. of tap water using a small funnel. The time taken is then 10–15 minutes. Between catheterizations she covers the stoma with a swab which is held in place by her tights. The skin around the ileostomy is unmarked. She has never been caused any embarrassment by the ileostomy and goes out and about with confidence. She feels no desire to have an ileostomy appliance and does not possess one.

Table II.—RESULTS OF OPERATION IN THE FIRST 4 PATIENTS IN THE PRESENT SERIES

CASE	DURATION (mth.)	CONTINENT	NO. OF CATHETERIZATIONS PER DAY	VOLUME OF POUCH AT 3 MONTHS (ml.)
1	15	Yes	3–4	150
2	14	No	—	200
3	7	Yes	2–3	250
4	5	Yes	3	150

Case 2, who had a rectus valve and no intussusception, never achieved complete continence of faeces. After catheterization of the reservoir the ileostomy would often remain continent for 3 or 4 hours and she might have a complete day without leakage. However, this would be unpredictable and quite large and troublesome leakages occurred on most days. These problems did not improve even when the pouch had had time to enlarge to a volume of 200 ml. She was accordingly fitted with an ileostomy bag and the ileostomy now functions in all respects like a conventional one. She will occasionally catheterize and empty the reservoir before going out socially, since this at least ensures that the ileostomy bag will remain empty for several hours. Fortunately in these early cases the patients were all given a short ileostomy spout placed in the conventional site so that management with an ileostomy bag is practicable. She has no skin problems.

The operation was most strikingly successful in *Case* 3, who was bedridden and incontinent with prolapse of a conventional ileostomy. She had a rectus valve and intussusception on the efferent loop. After formation of the reservoir ileostomy she remained completely continent of faeces, the catheter being passed every 8 hours and the average daily volume of effluent being about 400 ml. Her daughter was taught how to pass the catheter. The badly damaged skin around the ileostomy site rapidly healed and the burden of nursing care from this point of view was reduced to three 15-minute periods daily. The improvement in her physical condition was paralleled by a striking improvement in her mental state. She said that she felt clean again for the first time since her original proctocolectomy. She remained continent of faeces until her death 7 months later from bronchopneumonia complicating simple closure of a large perforated gastric ulcer.

Case 4 was discharged from hospital 3 weeks after a one-stage proctocolectomy with formation of a Kock ileostomy. She has now had the reservoir for 5 months. She passes the catheter two or three times a day and is completely continent of faeces between catheterizations. There is an occasional escape of gas but this has never been such as to cause her any social inconvenience. She has had only two episodes of leakage of faeces. One of these occurred after having had a traditionally large Christmas dinner when she forgot to pass the catheter for 10 hours. The other leakage occurred while she was suffering from a 24-hour attack of 'gastro-enteritis'. These episodes were insufficient to undermine her confidence and she has no desire to wear an ileostomy bag. The skin around the ileostomy has remained in perfect condition. She has now gone off on holiday to Majorca—perhaps as striking evidence of her sense of security as could well be devised.

Radiological Assessment.—Cine-cystography combined with simultaneous pressure recording as used in studying urinary-bladder dysfunction (Bates and Corney, 1971) has proved to be a most useful method of obtaining an objective assessment of the function of these reservoirs.

Such studies on these reservoirs have shown that as the reservoir fills the pressure in it rises slowly and steadily to 30–40 cm. of water. At about this pressure reflux occurs up the afferent loop. Although 'peristaltic' waves can be seen passing over the surface of the reservoir as it fills, these are not accompanied by any sudden increases in pressure within the pouch. The volume recorded in *Table II* is the volume held by the reservoir before reflux up the afferent loop occurs. After reflux has occurred pressure waves do occur in the pouch and these can be seen to coincide with the arrival of peristaltic waves from the afferent loop. These studies show also that the volume held by the pouch increases to about 200 ml. within 3 months of its formation.

If the catheter is removed when the pouch is full the mechanism of continence under stress can be examined by asking the patient to cough. Under these circumstances there is a sudden pressure wave in the reservoir owing to transmitted intra-abdominal pressure. It has been possible to demonstrate in this way that both the rectus valve and the intussusception can maintain continence.

Post-mortem Assessment.—The death of *Case* 3, 7 months after the formation of her ileostomy reservoir, provided an opportunity to study the appearance of a well-functioning reservoir at this interval. The reservoir formed an approximately spherical pouch some 10 cm. in diameter, with a volume on distension of 350 ml. The wall of the pouch was 2·5 mm. thick and was lined by a flattened mucosa (*Figs.* 6, 7). There was no evidence of muscular hypertrophy in the wall of the afferent loop.

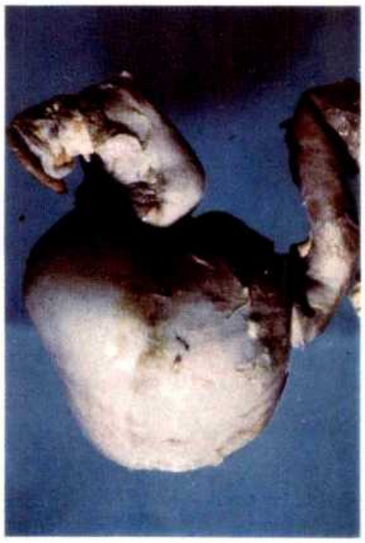

FIG. 6.—*Case* 3. Post-mortem appearance of the reservoir at 7 months.

The intussusception in this case had not been fixed internally with black silk sutures and it is evident that it has partially reduced. Microscopic examination showed a striking change in that the villi had disappeared and the mucosa consisted of parallel, straight, tubular glands lined with many mucus-secreting cells. It therefore resembled colonic mucosa.

DISCUSSION

An ileostomy reservoir which is to function satisfactorily in the way described above should have certain characteristics. It should be capable of accommodating about one-quarter of the daily ileostomy output without reflux. The valve mechanism on the efferent loop should be capable of withstanding the transient high intra-abdominal pressures transmitted to the reservoir on coughing, straining, etc. The reservoir itself should not respond to filling by developing co-ordinated expulsive contractions which would continually stress the efferent-loop valve mechanism. Catheterization of the efferent loop should be easy and therefore safe, and emptying of the reservoir should proceed fairly rapidly thereafter. Finally, continence must be able to be guaranteed so that the patient feels secure without any apparatus. Moreover, without such certainty some of the advantages of the continent ileostomy would be lost since the stoma could not then be made flush with the skin and could not be brought out low on the abdominal wall.

The results reported here suggest that the Kock ileostomy meets most of these requirements. The volume of ileostomy effluent varies considerably in different patients. However, a volume of about 500 ml. a day would be usual and volumes in excess of 1000 ml. a day probably indicate malfunction (Smiddy, Gregory, Smith, and Goligher, 1960). The reservoir volumes at 3 months (150–250 ml.) reported here would therefore be in the correct range to contain one-quarter to one-third of the daily effluent. It should be noted that these volumes were the volumes held by the reservoirs before reflux occurred. Kock, who measures the volume of the reservoir by distending it with a balloon until the patient feels slight discomfort, found volumes of about 500 ml. at 3 months in his patients (Kock, 1971).

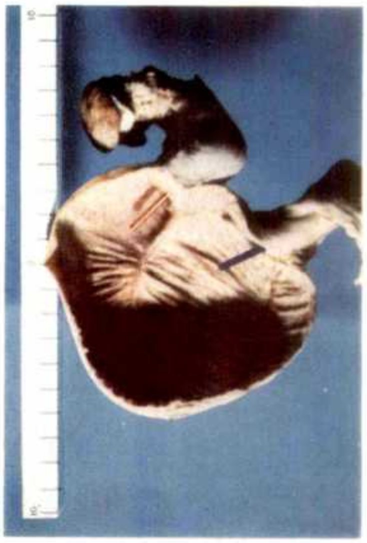

FIG. 7.—*Case* 3. Post-mortem appearance of the reservoir with the anterior half removed.

The radiographic studies in these cases showed that both the rectus valve and the intussusception were capable of maintaining continence when there was raised intra-abdominal pressure due to coughing and straining. However, Kock has found in his much larger series that the rectus valve is less reliable in this regard than the intussusception, which he now uses exclusively. The patient in the present series who failed to achieve continence had a rectus valve alone.

The radiographic studies in all these cases also confirmed that as the reservoir fills the pressure in it rises slowly and steadily to about 30 cm. of water with no sudden peaks due to expulsive contractions.

Catheterization of the efferent loop presents little difficulty when an intussusception only has been made and the technique is easily mastered by the patient. With a rectus valve catheterization may be more difficult owing to the oblique nature of the course through the rectus muscle.

Finally, only 1 patient out of the 4 assessed here at 3 months was incontinent of faeces. This patient had a rectus valve only. Kock (1971) achieved faecal continence in 22 out of 25 patients using a rectus valve in some and an earlier variety of the intussusception procedure in others. His own series now includes over 90 patients and he has found that using the technique of intussusception described here the proportion of patients with faecal continence is greatly increased as is the proportion who are also continent of gas (Kock, 1973). An overall assessment of the safety and reliability of the procedure must clearly await the publication of Kock's own results in this much larger series. However, the cases reported here confirm that this technique can produce highly satisfactory results in selected patients.

Acknowledgements.—I wish to express my gratitude to Professor Kock for introducing me to this procedure and teaching me the technique and for much helpful advice and criticism. I am also indebted to Mr. W. W. Slack for collaborating with me in the treatment of 2 of these patients.

HIGHLY SELECTIVE VAGOTOMY WITHOUT A DRAINAGE PROCEDURE IN THE TREATMENT OF HAEMORRHAGE, PERFORATION, AND PYLORIC STENOSIS DUE TO PEPTIC ULCER

BY D. JOHNSTON, P. J. LYNDON, R. B. SMITH, AND C. S. HUMPHREY
UNIVERSITY DEPARTMENT OF SURGERY, THE GENERAL INFIRMARY, LEEDS

SUMMARY

The good results of highly selective vagotomy (H.S.V.) in the elective surgical treatment of uncomplicated duodenal ulcer led to its use in the treatment of 30 patients who were suffering from complications of peptic ulcer, over a period of 21 months. In the emergency situation it is vital to select for H.S.V. patients who are fit enough to withstand a 1–2-hour operation.

Five out of a total of 9 patients with perforated duodenal ulcer were deemed to be suitable for H.S.V. In contrast, H.S.V. was used in the treatment of all 10 patients with haemorrhage (5 patients with duodenal ulcer and 5 with gastric ulcer), because definitive treatment for the ulcer is essential after haemorrhage has been arrested by direct suture.

Pyloric stenosis was diagnosed in 15 of 75 patients who came to elective surgery for duodenal ulcer. The diagnosis was made on clinical and radiological grounds and was confirmed at operation. Seven of the 15 patients had concomitant gastric ulceration. All 15 patients were treated by H.S.V. without a drainage procedure. The stenosis was simply dilated digitally. Seven patients who were followed up for at least a year underwent barium-meal examination, which showed that gastric emptying was normal in each case and that there was no sign of recurrent ulceration.

There was no operative mortality. None of the patients with haemorrhage bled again after operation. Only 1 of the 30 patients developed gastric retention, which was transient. Of the 14 patients who were reviewed more than 1 year after H.S.V., 11 had a perfect clinical result, 2 were very good, and 1 was 'fair' (Visick grade 3). The long-term prognosis should be the same as that of patients who have undergone elective H.S.V.

Granted a modicum of case selection, H.S.V. is a safe operation in the treatment of emergencies such as haemorrhage or perforation. In pyloric stenosis H.S.V. preserves and makes use of the stomach's compensatory mechanisms of hypertrophy and hyperperistalsis, whereas both gastrectomy and vagotomy with drainage destroy them. Vagotomy of the entire stomach makes necessary the addition of a drainage procedure. Vagotomy with drainage impairs the ability of the antrum to 'mill' food and to propel chyme onwards, and destroys or by-passes the pyloric sphincter. These surgical insults to normal gastric physiology harm the patient by producing dumping, diarrhoea, bilious vomiting, steatorrhoea, and gross elevation of serum gastrin. The main conclusion of this paper is that such harm can be avoided, because it is shown that even patients with pyloric stenosis can be treated by H.S.V. without a drainage procedure. The routine use of complete gastric vagotomy with a drainage procedure in the elective surgical treatment of duodenal ulcer is no longer justified.

Two hundred and fifty patients with duodenal or gastric ulceration have been treated by highly selective vagotomy without a drainage procedure (H.S.V.) (Johnston and Wilkinson, 1969, 1970) in Leeds in the past 4 years. Operative mortality was nil, only 1 patient required the addition of a drainage procedure, and none has developed a recurrent ulcer. H.S.V. was found to reduce acid output as effectively, for up to 2 years, as did truncal or selective vagotomy with drainage (T.V.+D., S.V.+D.) (Johnston, Wilkinson, Humphrey, Smith, Goligher, Kragelund, and Amdrup, 1973), while gastric emptying was much closer to the normal after H.S.V. than after T.V./S.V.+D. (Humphrey and Wilkinson, 1972; Wilkinson and Johnston, 1973). In consequence, side-effects such as dumping and diarrhoea were reduced significantly (Humphrey, Johnston, Walker, Pulvertaft, and Goligher, 1972; Johnston, Humphrey, Walker, Pulvertaft, and Goligher, 1972). The overall clinical results (Visick, 1948) as assessed at the Leeds Gastric

Follow-up Clinic 2 years after operation were much better after H.S.V. than after T.V./S.V.+D. (Johnston, Goligher, Pulvertaft, Walker, Amdrup, and Jensen, 1972).

This felicitous experience with the new operation encouraged us to use it in patients who were suffering from complications of peptic ulcer. H.S.V. has been used in the treatment of a few carefully selected patients with perforated duodenal ulcer. It has also found wide application in the treatment of patients with haemorrhage or pyloric stenosis. The operation can be done fairly quickly, usually within 90–120 minutes.

PERFORATION

Patients.—Five slim men with perforated duodenal ulcer who were less than 60 years of age were treated by H.S.V. Further details are given in *Table I*. They were selected for H.S.V. out of a total of 9 patients who came to emergency operation for perforated duodenal ulcer in the same period. Three of the remaining 4 patients were treated by simple suture of the perforation, and 1 by truncal vagotomy and pyloroplasty. H.S.V. was used, first, if definitive surgery to cure the ulcer was indicated because of recurrent pain, previous haemorrhage, or perforation, and, secondly, if the patient was thought to be fit enough to withstand an operation which takes from 1 to 2 hours to perform. Thus, H.S.V. is usually contra-indicated in patients over 60 years of age, in the obese, and in those with a history of cardiac or respiratory disease. In addition, patients should arrive in the operating theatre within 8 hours of perforation, and soiling of the peritoneal cavity should not be gross.

* M.A.O.pg, Maximum acid output to a dose of pentagastrin of 10 μg. per kg. intramuscularly.
† Insulin test was judged positive or negative by Hollander's (1948) criteria.
‡ P.A.O.I is the peak 30-minute acid output × 2, minus the basal acid output. Dose of insulin was 0·2 U per kg. intravenously.
§ Patient's symptoms of epigastric discomfort probably attributable to incisional hernia.

Operative Procedure.—A midline epigastric incision was used. The diagnosis having been confirmed, peritoneal toilet was performed, the perforation closed, and H.S.V. performed as expeditiously as possible.

Postoperative Progress.—Recovery was uneventful in each of the 5 patients although 1 developed a wound infection. Gastric retention did not occur. The insulin test (Hollander, 1948) was negative in each case. The mean length of stay in hospital after operation was 9·6 days (range, 8–13 days).

Clinical Result.—Three patients were reviewed in the Gastric Follow-up Clinic 1 year after operation. One had a perfect result (Visick grade 1), 1 was nearly perfect (Visick grade 2), and 1 was graded Visick 3 on account of symptoms attributable to an incisional hernia, which has since been repaired. The 2 remaining patients are in excellent health, 3 and 6 months respectively after operation.

HAEMORRHAGE

Patients.—All 10 patients were suffering from moderate to severe haemorrhage, which either did not stop or recurred after the patient's admission to hospital. The volume of blood transfused preoperatively ranged from 6 to 9 pints, with a mean of 7·2 pints. Five of the patients had chronic duodenal ulceration, 4 had chronic gastric ulceration, and 1 had two acute gastric ulcers. Further details are given in *Table II*. These 10 patients form a *consecutive* series of patients with upper gastro-intestinal bleeding who were operated upon as emergencies by one of us (D. J.) in the past 2 years. Four of the 10 patients were relatively high-risk cases (*Table II*): *Case* 2 was 71 years old and obese, *Case* 5 had recently undergone her second mitral valvotomy, *Case* 6 had cirrhosis of the liver and carcinomatosis, and *Case* 10 was 61 years old and obese, and her systolic blood-pressure was 50 mm. Hg at the time of admission to hospital.

Preoperative Management.—Patients were admitted under the care of a physician, who then asked the surgeon for an opinion. This request was usually made soon after the patient's admission to hospital. A barium-meal examination was performed in the department of radiology as a matter of urgency, if the patient was well enough. Gastroscopy was used, not routinely but in an attempt to gain additional information when the diagnosis was obscure. Patients over the age of 50 who had bled severely (requiring transfusion of more than 4 pints of blood in 24 hours) and who were known to have a chronic gastric or duodenal ulcer were usually operated upon as soon as they had been adequately transfused, without being given a chance to bleed again. Younger patients were accorded the privilege of having a second bleed.

Operative Procedure.—To save time a midline incision was used. Access to a gastric ulcer was obtained by means of a longitudinal gastrotomy, which was placed carefully along the greater curvature if the ulcer was within 8 cm. of the pylorus in order to avoid damage to the nerve-supply of the antral 'pump'. A duodenal ulcer was approached by a 5-cm. longitudinal incision in the anterior wall of the duodenum which reached the pyloric ring but did not transect it. This incision gave adequate access to the ulcer in 4 of the 5 patients with duodenal ulcer. The fifth patient (*Case* 10, *Table II*) was obese and had a particularly deep penetrating ulcer, access to which was obtained only when a 10-cm.-long gastropyloroduodenotomy had been performed. All these incisions, including the last one, were closed as they had been made, longitudinally. Edge-to-edge apposition without inversion was the aim. When the diagnosis was in doubt and no lesion could be seen or felt at the time of operation a long gastrotomy was performed and the whole of the gastric mucosa was inspected. If this search proved unrewarding a duodenotomy was done but the pylorus was not divided. When the ulcer was found its base was underrun with several deeply placed 0 Mersilene sutures. The entire epithelial margin of a gastric ulcer was excised and sent for histological examination. The mucosal defect in the stomach or duodenum was closed with interrupted catgut sutures. The gastrotomy or duodenotomy was then closed with

continuous catgut reinforced by seromuscular sutures of interrupted catgut in the stomach and by interrupted fine silk in the duodenum, without inversion. The operation was completed by the performance of H.S.V., which was done as quickly as possible, usually in 30 or 40 minutes.

Postoperative Progress.—None of the patients re-bled either in hospital or later and none developed gastric retention. All eventually made a good recovery, although convalescence was marred in several by a minor degree of chest infection. The worst complication occurred in the patient in whom a gastroduodenotomy had been closed longitudinally rather than as a pyloroplasty. She developed a duodenal fistula on the ninth postoperative day but fortunately this closed spontaneously within 2 days.

Clinical Result.—At the Gastric Follow-up Clinic each of the 3 patients who were reviewed 1 year after operation was considered to have achieved a perfect (Visick grade 1) clinical result. Three patients were reviewed 6 months after operation: 1 had a perfect result and 2 had very good results (Visick grade 2).

PYLORIC STENOSIS

Definition.—The diagnosis of pyloric stenosis was based on the presence of one or more of the following features: a history of copious and repeated vomiting (particularly if the vomitus contained food which had been eaten on the previous day), the finding of a succussion splash 3 hours or more after the last meal, gastric 'resting juice' of more than 250 ml. and containing food residues after an overnight fast, and finally the demonstration of the typical radiological features of pyloric stenosis. In all except 1 of the 15 patients the diagnosis was confirmed at laparotomy, when the pyloroduodenal channel was found not to admit the distal interphalangeal joint of the index finger or a No. 14 Hegar's dilator (Kirk, 1970).

Patients.—Fifteen patients (20 per cent of *all* the patients coming to elective surgery for duodenal ulcer in the past 21 months) were found to have pyloric stenosis. All 15 cases were treated by H.S.V. plus digital dilatation. The stenosis was of varying degree. In some patients spasm and oedema probably contributed to the gastric obstruction because simple rest in bed before operation, supplemented if necessary by once-daily gastric lavage, led to the cessation of vomiting and disappearance of the succussion splash. It then became possible to re-hydrate the patient by the oral route. Five of the 15 cases could be classified on these grounds as having mild pyloric stenosis. At the other end of the spectrum none of the 15 patients could be regarded as having late neglected pyloric stenosis because none had visible gastric peristalsis, a palpable stomach, or gross dehydration associated with severe uraemia or tetany. Nevertheless, the fact that no fewer than 7 of the 15 patients had concomitant gastric ulceration is suggestive of a moderately severe degree of gastric obstruction. In addition, a tight unyielding fibrous stricture was found in most patients at the time of operation (*Table III*).

The 15 patients consisted of 9 men and 6 women whose mean age was 54 years. This is 14 years older than the mean age of patients coming to surgery for duodenal ulcer (D.U.) *without* pyloric stenosis. Their mean weight was 56 kg., which is 7 kg. less than that of the average D.U. patient coming to operation. Their mean loss of weight before operation was 6 kg. (*Table III*). Most of these patients had suffered from the pain of their ulcer for many years, the mean length of history being 21 years, compared with 10 years in the average D.U. patient coming to surgery.

Operative Procedure.—

1. *Highly Selective Vagotomy.*—H.S.V. is a delightfully easy operation in these patients, both on account of their lean build and because the nerves of Latarjet are prominent. It is important to leave a generous length of stomach innervated, first, because the stomach is usually dilated so that the *proportion* which is left innervated may be little greater than usual, and, secondly, because in the absence of a drainage procedure gastric emptying depends upon the vigour of antral peristalsis. Hence the necessity of preserving the motor nerve-supply to the antral 'pump' is obvious. The mean length of pre-pyloric stomach left innervated was 8·2 cm., compared with 6·5 cm. in patients with uncomplicated duodenal ulcer.

2. *Dilatation of the Stenosis.*—A small gastrotomy is made in the denervated portion of the stomach and the index finger is inserted. In 50 patients with D.U. *without* the clinical or radiological features of pyloric stenosis we have found that the pylorus and duodenum will admit the distal interphalangeal joint of the index finger and at least a No. 14 Hegar's dilator. This is in accord with Kirk's observations (Kirk, 1970). By these criteria 14 of the 15 patients had stenosis, which was usually post-pyloric rather than truly 'pyloric'. The fifteenth patient had a widely patent pyloric channel, on one side of which there was an active gastric ulcer and on the other an active duodenal ulcer. The spasm and oedema produced by these ulcers had presumably caused functional obstruction to gastric emptying. In most patients the degree of stenosis was so severe (*Table III*) that only very narrow Hegar's dilators could be passed. The stenosis was gently but firmly dilated with the tip of the index finger, and the 'sphincter' gradually stretched until it admitted both the distal and the proximal interphalangeal joints. Since the stricture was fibrous and unyielding this dilatation was usually felt to rupture scar tissue and indeed in 4 patients it produced frank perforation of the anterior duodenal wall. These perforations were closed transversely with interrupted catgut sutures. In no instance was the pyloric ring or the distal antrum disrupted.

3. *Management of Concomitant Gastric Ulcer.*—This was treated in the manner which we have described previously (Johnston, Humphrey, Smith, and Wilkinson, 1972). The ulcer was excised by a transgastric approach and confirmation that it was benign was obtained by frozen-section examination. The mucosal defect was closed with catgut sutures. When the ulcer is within 8 cm. of the pylorus, as was the case in 5 of the 7 patients, there is no need to separate the nerves of Latarjet from the base of the ulcer. When the gastric ulcer is proximal to the incisura, however, as it was in 2 patients, a tedious dissection through oedematous fibrosed tissues in the ulcer base may be required. On the other hand, since the alkaline zone of the stomach has been shown to extend from the pylorus proximally as far as the

proximal margin of the gastric ulcer (Oi, Oshida, and Sugimura, 1959) it is probably unnecessary to lay bare the lesser curve as low down as the incisura. It may be sufficient to begin the dissection at the *upper* margin of the gastric ulcer. This certainly renders the operation much easier technically, reduces the risk of damage to the nerves of Latarjet, and makes H.S.V. more acceptable as a routine procedure for gastric ulcer. A 'proximal H.S.V.' of this type was used in 1 case in this series. Despite the fact that 13 cm. of stomach were left innervated the insulin test performed 1 week after operation was negative.

Postoperative Progress.—No patient developed gastric retention in the postoperative period. All 15 patients made a good recovery, although wound infection and chest infection were both fairly common (*Table III*).

One patient (*Case* 6, *Table III*) was readmitted to hospital 3 months after operation with a complaint that she was vomiting food almost every day. She could eat only small meals and had failed to gain weight. Barium-meal examination showed that gastric emptying was slow, although there was no sign of recurrent ulceration. She was treated conservatively, first with a liquid diet, then with 'sloppy' foods. She gradually regained the ability to eat solids without vomiting. A barium-meal examination 7 months after operation showed that gastric emptying was within normal limits and that there was no sign of duodenal or of gastric ulceration.

The remaining 14 patients have no symptoms or signs of gastric retention. Barium-meal examination was performed in the 7 patients who had been followed up for 1 year. In each case gastric emptying was reported to be normal, and although deformity of the duodenal cap remained there was no sign of recurrent ulceration.

Clinical Result.—Seven patients were reviewed at the Gastric Follow-up Clinic 1 year after operation.

§, Positive in the second hour.

Six were judged to have achieved a perfect (Visick grade 1) clinical result, and one had a very good (Visick grade 2) result. Of the remaining patients, 1 has been lost to follow-up, 1 is the patient with transient gastric retention who now has a 'fair' (Visick grade 3) result, and the remaining patients are known to be progressing well on shorter periods of follow-up.

DISCUSSION

The absence of operative mortality in this series of 30 patients with severe complications of peptic ulcer who were treated by H.S.V. is gratifying, particularly because the patients with haemorrhage and with pyloric stenosis were *consecutive* patients suffering from these complications, while the 5 patients with perforation were selected out of a total of only 9. Two hundred and fifty patients have been treated by H.S.V. in Leeds in the past 4 years without mortality. H.S.V. is thus an extremely safe operation. This safety may be due in part to the absence of an anastomosis and in part to the postoperative convalescence which is usually uneventful. Indeed, provided that haemostasis is perfect and wound closure secure there is little to go wrong, apart from the general complications of anaesthesia and surgery. There is no problem with a 'loop' or stoma, as in gastro-enterostomy or Polya gastrectomy, no duodenal stump to leak, and the disturbances of motility which occasionally delay convalescence after truncal vagotomy with a drainage procedure have not been encountered. After H.S.V. patients are routinely managed without either a nasogastric tube or an intravenous drip. Nursing is thereby simplified and the patients are free to move around and to walk about the ward.

The main aim in the treatment of emergencies such as haemorrhage and perforation is, of course, to save life. The quality of that life is a secondary, if important, consideration. The surgeon must exercise judgement both in deciding whether or not, and when, to operate, and then in choosing which operation to perform. In the treatment of perforated duodenal ulcer simple suture is the simplest and safest method. Definitive procedures such as vagotomy with drainage or H.S.V. should be used only in carefully selected patients, who are *relatively* young and fit, not shocked, and in need of cure of a troublesome chronic ulcer. The surgeon obviously should choose a procedure with which he is familiar. We would merely suggest that if definitive surgery *is* indicated, H.S.V. in the hands of those who use it frequently will not carry a higher mortality than does vagotomy with drainage and it will yield better clinical results.

If H.S.V. has only a limited place in the surgical treatment of perforated ulcer it would seem to merit much wider application in the treatment of haemorrhage, if only because definitive surgery is indicated in all patients coming to surgery for haemorrhage whereas the same is not true for perforation. In the treatment of bleeding *duodenal* ulcer, vagotomy with underrunning of the ulcer has been shown to be safer than partial gastrectomy (Carruthers, Giles, Clark, and Goligher, 1967; Farris and Smith, 1967; Williams, 1969; Schiller, Truelove, and Williams, 1970). But which type of vagotomy? The choice would appear to lie between truncal vagotomy with drainage and H.S.V. H.S.V. takes about 30 minutes longer to perform than does truncal vagotomy with a drainage procedure, and for this reason should probably not be used in patients with massive haemorrhage who have a low blood-pressure immediately before or during operation, in patients over the age of 70, or in those who have severe cardiac or respiratory disability. The presence of obesity is also a relative contra-indication to H.S.V. In case of doubt it is advisable to ask the anaesthetist if he thinks that an additional 30 minutes' operating would entail an added risk to life.

In 4 out of 5 cases of bleeding duodenal ulcer, duodenotomy without transgression of the pylorus gave adequate access to the ulcer. In the fifth case it was necessary to perform a wide gastroduodenotomy. All these incisions were sutured longitudinally, without pyloroplasty. The technical difficulties (and dangers) of attempting to reconstitute a divided pylorus in the presence of oedema and fibrosis could, however, be formidable in some patients with duodenal ulcer. Leakage and stenosis are two of the potential hazards.

Haemorrhage from a *gastric* ulcer is a different problem which many surgeons still treat by gastric resection, reserving vagotomy, drainage, and suture of the ulcer for use in special circumstances such as an ulcer near the cardia or a poor-risk patient. It is therefore interesting to note that Schiller and others (1970) found that the operative mortality was nil in 15 patients with gastric ulcer who were treated by vagotomy and drainage, whereas it was 10 per cent in 81 patients who were treated by Billroth-I gastrectomy, and 19 per cent in 27 patients who were treated by Polya gastrectomy. Again, Williams (1969), in a review article, stated that the post-operative mortality for bleeding gastric ulcer treated by gastrectomy was 25 per cent, compared with 9 per cent after vagotomy with pyloroplasty. These figures must be viewed with caution since the comparisons are not of controlled series, but they do suggest that vagotomy with drainage is safer than gastrectomy. In Leeds H.S.V. has yielded good clinical results in the *elective* treatment of gastric ulcer for up to 3 years (Johnston and others, 1972) and fears that gastric emptying would be delayed have not been confirmed. Whether the incidence of recurrent ulceration will be as low after H.S.V. as after Billroth I-gastrectomy remains to be established. Of the technical considerations in the performance of H.S.V. for gastric ulcer, the most important is that the ulcer should be excised to exclude the possibility of malignancy. The approach to the ulcer should be from inside the stomach to reduce the chance of damage to the nerves of Latarjet. The most novel and exciting consideration, however, is that a *very proximal* H.S.V. (above the ulcer) may suffice to denervate the entire acid-secreting portion of the stomach (Oi and others, 1959).

Fifteen patients with pyloric stenosis were treated by H.S.V. plus pyloric 'sphincter stretch'. Only 1 patient subsequently developed gastric retention, which was transient, and barium-meal examination in the 7 patients who were followed up for at least 1 year showed that gastric emptying was satisfactory. Although the pattern of emptying of barium does not necessarily reflect the pattern of emptying of a normal meal the radiological findings are fully supported by the clinical results, because none of the patients complains of vomiting and 6 out of 7 patients who were reviewed at the Gastric Follow-up Clinic 1 year after operation were judged to have a perfect clinical result. The obvious objection to the use of simple dilatation for pyloric stenosis is that re-stenosis will take place as the ulcer heals, but this does not seem to have occurred. If gastric retention has not developed within 6–12 months of operation it is unlikely to do so subsequently.

As mentioned earlier, 5 of the 15 patients had quite a mild degree of stenosis which was made worse by the oedema and spasm associated with an active ulcer. There is no doubt, however, that the stenosis was moderate to severe in 10 patients; severe enough, indeed, to cause hypertrophy and dilatation of the stomach and to produce secondary gastric ulceration in no fewer than 7 of the 10 patients. So tight was the stenosis in 4 patients that gentle dilatation with one finger produced actual perforation of the anterior duodenal wall. Our preliminary experience would thus suggest that pyloric stenosis of this degree can be treated successfully without the need for a drainage procedure or for gastric resection. None of the patients, however, exhibited the severe dehydration, tetany, or the vast atonic stomach which characterize late, neglected pyloric stenosis. Patients with such very advanced pyloric stenosis would be unsuitable for treatment by H.S.V. plus sphincter stretch.

The finding of satisfactory gastric emptying after H.S.V. for pyloric stenosis is relevant to the surgical management of patients with duodenal ulcer who do *not* have pyloric stenosis, because it implies that none of them need have a drainage procedure added. This in turn means that there is no need to expose patients with uncomplicated duodenal ulcer to the *relatively* high incidence (compared with that which follows H.S.V.) of diarrhoea, early dumping, and bile vomiting which follows truncal or selective vagotomy with a drainage procedure. Indeed, by extending the use of H.S.V. to patients with haemorrhage, perforation, and pyloric stenosis we have been able to treat 100 consecutive patients with duodenal ulcer in the past 2 years without the addition of a drainage procedure. Presumably H.S.V. plus dilatation provides effective treatment for pyloric stenosis because, by preserving the nerves to the antrum, it preserves and uses the compensatory mechanisms of hypertrophy and hyperperistalsis which the stomach has developed in an attempt to overcome the obstruction at its outlet. The conventional operations such as gastrectomy or vagotomy with drainage accord these compensatory mechanisms no such respect.

Acknowledgements.—It is a pleasure to thank our colleagues Dr. F. R. Ellis and Dr. W. D. A. Smith of the Department of Anaesthetics, The General Infirmary, Leeds, for their help with these cases. We are indebted to Dr. K. C. Simpkins who performed most of the follow-up barium-meal examinations. Professor J. C. Goligher and Dr. B. E. Walker kindly permitted us to include data from the Leeds Gastric Follow-up Clinic. We would also like to thank Mrs. Elaine Nutter who typed the manuscript.

Dr. P. J. Lyndon and Dr. R. B. Smith were supported by grants from the Board of Governors of the United Leeds Hospitals.

A REVIEW OF 15 YEARS' EXPERIENCE IN THE USE OF SCLEROTHERAPY IN THE CONTROL OF ACUTE HAEMORRHAGE FROM OESOPHAGEAL VARICES

BY GEORGE W. JOHNSTON AND HAROLD W. RODGERS
ROYAL VICTORIA HOSPITAL, BELFAST

SUMMARY

The results of 15 years of sclerotherapy for acute variceal haemorrhage are reviewed retrospectively. One hundred and seventeen patients with portal hypertension received a total of 217 injections. Haemorrhage was controlled in 93 per cent of admissions. The mortality per injection was under 12 per cent, and the total admission mortality was 18 per cent. Even where a subsequent shunt was impracticable, sclerotherapy provided useful palliation with few serious complications.

IT is generally agreed that some form of portal systemic shunt is the most effective means of preventing haemorrhage from oesophageal varices in a patient with portal hypertension. Unfortunately a shunt is not always possible or even desirable; for example, in patients under the age of 10 years with portal vein thrombosis where a shunt is impracticable, and in the acute bleeding episode in patients with cirrhosis, of whom only a few with good liver function are suitable for emergency or urgent portacaval shunt. Indeed, the majority of these patients with cirrhosis who survive the acute haemorrhage never become acceptable for a shunt because of advanced years or poor liver function. Even in the best surgical circles a small percentage of 'post-shunt bleeders' are found, particularly in patients with portal vein thrombosis —these present yet a further problem. It is in all these situations that we find sclerosing injections particularly useful. It is not suggested that this form of therapy is an alternative to a shunt; it is merely a further weapon in our therapeutic armoury. Although this form of treatment was first described by Crafoord and Frenckner in 1939 and was introduced to the British Isles in 1955 by Macbeth it has not been universally accepted. The technique described here has been used in Belfast, with few modifications, since 1958.

METHODS

On admission the patient is resuscitated with fresh blood and a Sengstaken tube is passed to limit blood-loss. In addition, neomycin, *Lactobacillus*, and lactulose are introduced into the bowel via the Sengstaken tube to reduce the risk of portal systemic encephalopathy. Injection therapy is delayed for some hours, thus allowing this régime to take effect and the patient to become haemodynamically stable.

In adults a 50-mm. Negus rigid oesophagoscope with proximal fibre lighting is passed under general anaesthesia. In children the largest instrument which can be passed with safety is used. A rigid wide-bore instrument is required to distend the varices prior to injection and to compress them following injection. Initially the oesophagoscope is passed right down to the cardia and this controls bleeding in virtually every patient. In our experience it is extremely rare to find bleeding originating in varices below the cardia. The instrument is then withdrawn a few centimetres, allowing the varices to bulge into the lumen (*Fig.* 1A). Using a Macbeth needle, 2–3 ml. of ethylolamine oleate (Varistab) are injected into each varix; up to 15–25 ml. of sclerosant are used at each session. The aim is to perform an intravascular injection, though undoubtedly some sclerosant goes outside the vein wall. Bleeding from each injection site is immediately controlled, either by pressure from a small swab or by advancing the oesophagoscope over the puncture wound (*Fig.* 1B). Following injection a Sengstaken tube is usually inserted to produce tamponade for a few hours and thus aid the initiation of vascular sclerosis.

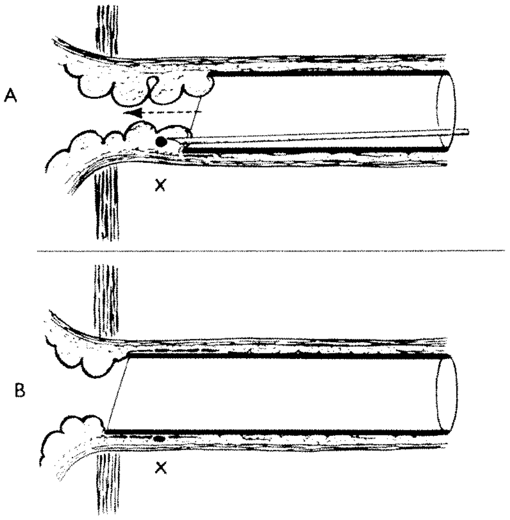

FIG. 1.—A, Showing varices bulging into the lumen of the oesophagoscope, thus facilitating injection at point X. B, The oesophagoscope is advanced over the puncture wound X to control bleeding.

PRESENT SERIES

Patients reviewed.—During the 15-year period from 1958 to 1972, 117 patients received a total of 217 injections. In 87 patients the portal hypertension was due to intrahepatic block, chiefly cirrhosis. In 29 patients the obstruction was extrahepatic. One patient in the series had no demonstrable obstruction to the portal venous system (*Table I*). There was a predominance of females in all groups in the series. The ages ranged from 9 to 82 years in the intrahepatic group and from 6 months to 52 years in the extrahepatic group (*Table II*).

Control of Haemorrhage.—The 117 patients had 194 admissions when injection was carried out for acute variceal haemorrhage. Bleeding was controlled in 177 instances, giving a 93 per cent control rate. One injection was sufficient in 158 instances, but occasionally more than one injection was required (*Table III*). It should be pointed out that injection therapy was used only for episodes of acute bleeding and not prophylactically, as recently described by Pinel, Richard, Dentan, Troutoux, and Leger (1971).

Table I.—PATIENTS WITH ACUTE HAEMORRHAGE FROM OESOPHAGEAL VARICES TREATED BY INJECTION, 1958–72

OBSTRUCTION	NO. OF PATIENTS	NO. OF INJECTIONS
Intrahepatic	87	134
Extrahepatic	29	82
None	1	1
Total	117	217

Table II.—AGE AND SEX OF THE PATIENTS IN THE PRESENT SERIES

OBSTRUCTION	AGE AND SEX	AGE RANGE (yr.)	MEAN (yr.)
Intrahepatic	51 F. 36 M.	9–82	56
Extrahepatic	20 F. 9 M.	½–52	20
None	1 F.	58	58

Table III.—RESULTS OF TREATMENT BY SCHLEROTHERAPY OF 194 ADMISSIONS FOR VARICEAL BLEEDING

NO. OF INJECTIONS	BLEEDING CONTROLLED	BLEEDING UNCONTROLLED
1	158	15
2	18	1
3	1	1
Total	177*	17

* Ninety-three per cent control rate.

Hospital Mortality.—In the 15 years under review there were 35 hospital deaths during 194 admissions. Nineteen deaths occurred even after bleeding had been controlled; 10 of these patients died as a result of hepatic coma, 6 from unrelated pathology, and 3 following elective portacaval shunt during the same hospital admission. Sixteen deaths occurred where bleeding was not controlled; 10 from continuing haemorrhage and 6 following further emergency operations, one of which was for a coexisting bleeding duodenal ulcer. This gives a total admission mortality of 18 per cent, but the mortality per injection was under 12 per cent. We would emphasize that injection therapy is used routinely for all admissions with acute variceal bleeding and there is no selection of patients. Only patients *in extremis* who do not live long enough to reach the operating theatre are excluded.

Long-term Effectiveness of Sclerotherapy.—Injection therapy reduces the frequency and severity of haemorrhage and occasionally permanent sclerosis occurs. At subsequent oesophagoscopy the varices are of smaller calibre and sometimes they are no longer visible (Johnston and Rodgers, 1964). For example, 1 boy with portal vein thrombosis required seven series of injections for acute haemorrhage between the ages of 15 and 20. Since then he has been free from bleeding for almost 10 years and now has no evidence of varices. In patients coming to autopsy after injection therapy histological examination of the submucous veins of the oesophagus has shown organized intraluminal thrombosis, intimal thickening, and perivenous fibrosis to be the basis of haemorrhage control (Hunt, Johnston, and Rodgers, 1969).

Where a shunt is impossible and sclerotherapy has to be relied upon as the definitive treatment, significant control can be obtained. Thus, in the patients with cirrhosis the average period of relief from bleeding using injection therapy only was 10 months, and the maximum period of freedom in any one patient was 5½ years. In the extrahepatic group the average period of relief was 2½ years, and the longest period of freedom from haemorrhage was almost 15 years. The patient with no demonstrable block has not bled since being injected 8 years ago (*Table IV*).

Table IV.—Freedom from Haemorrhage following Injection

Obstruction	Average Relief	Maximum Relief
Intrahepatic	10 mth.	5½ yr.
Extrahepatic	30 mth.	15 yr.
None	8 yr.	8 yr.

Of course, where feasible some form of portal systemic shunt is performed as an elective procedure at a later date. We now feel that it is best to discharge the patient from hospital for a month or two to recuperate before performing the shunt. In this series only 28 of the patients with cirrhosis were subsequently considered fit for a shunt, and in the extrahepatic group only 10 patients had an elective shunt. The small number in the extrahepatic group is explained by the fact that some were 'post-splenectomy bleeders', some had previously failed shunts, and some are still too young for a splenorenal shunt.

Complications.—The procedure is remarkably free of complications, although it is not unusual for the patient to have a mild tachycardia, slight pyrexia, and sometimes retrosternal discomfort for 24–48 hours after injection. This is presumably due to oesophagitis and peri-oesophagitis from the irritant effect of the sclerosant. On 3 occasions the inflammatory reaction in the oesophagus was severe enough to cause delayed necrosis of the oesophageal wall with leakage. This occurred 5–10 days after the injection. Two of the patients were 11-year-old girls with portal vein thrombosis and severe thrombocytopenia. In both cases excess sclerosant was probably used in an effort to obtain haemostasis. One patient required a colonic replacement of the oesophagus but later developed an anastomotic leak and died. The other patient developed an empyema which required drainage. She subsequently had a splenorenal shunt and is now well and free from bleeding 7 years later. The other delayed perforation occurred in a 59-year-old male with alcoholic cirrhosis, causing death 19 days after injection. One other young girl with an extrahepatic block developed a temporary oesophageal stricture after receiving twelve injections in 9½ years (the largest number in this series). The stricture responded to one oesophageal dilatation and she has been free of dysphagia and bleeding for the past 4 years.

Follow-up.—Our follow-up extends from 3 months to almost 15 years from the first injection. In the cirrhotic group 36 patients survive, and 25 of the 29 patients with extrahepatic block are still alive. Three patients in the cirrhotic group have been lost to follow-up and are presumed dead.

DISCUSSION

In most reported series acute haemorrhage from oesophageal varices carries a mortality of around 50 per cent for the first hospital admission. This figure has not improved in the past 20–25 years and is unlikely to do so unless an effort is made to concentrate these patients in centres experienced in their therapy. The first priority is control of bleeding, and although a Sengstaken tube does this adequately initially, 40 per cent of patients re-bleed on release of the tamponade (Rothwell-Jackson and Hunt, 1968). Systemic vasopressin gives only temporary relief and is not without risk (Sherlock, 1967), and direct infusion of the drug into the superior mesenteric artery fares no better (Murry-Lyon, Pugh, Nunnerley, Laws, Dawson, and Williams, 1973). The Boerema-Crile operation of transthoracic ligation of the varices carries a mortality of 30–40 per cent when performed as an emergency procedure (Hunt, 1967), and has only a temporary effect. An emergency shunt is unlikely to save more than 50 per cent of cases unless patients are carefully selected (Edmondson, Jackson, Juler, Digel, and Perrin, 1971). Sclerotherapy carries a lower morbidity and mortality than any of these more usually accepted emergency measures and deserves to be more widely adopted. Without any patient selection the admission mortality is reduced to under 20 per cent.

CONCLUSION

Sclerotherapy is not advocated as a substitute for portal systemic shunt operations. However, in patients where a shunt is untenable it is a useful means of obtaining an appreciable survival rate, and carries a lower morbidity and mortality than the more usually adopted procedures.

URINARY HYDROXYPROLINE EXCRETION IN EARLY AND ADVANCED BREAST CANCER—A SEQUENTIAL STUDY

BY A. CUSCHIERI

DEPARTMENT OF SURGERY, UNIVERSITY OF LIVERPOOL, AND LIVERPOOL ROYAL INFIRMARY

SUMMARY

A sequential study of urinary hydroxyproline was performed in 47 patients with cancer of the breast. The results have shown that hydroxyproline excretion in the urine provides a sensitive index of the early development of secondary deposits in bone from primary breast cancer. Elevation of the urinary excretion of hydroxyproline may predate by several months the radiological demonstration of osseous deposits. Sequential estimations have shown that the elevated urinary hydroxyproline excretion is persistent in patients who subsequently develop deposits in bone.

MOST of the hydroxyproline (OH.P) in the urine originates from bone (Dull and Henneman, 1963; Klein, Lafferty, Pearson, and Curtiss, 1964) and the urinary excretion of this imino acid is mainly derived from the degradation of newly synthetized (soluble) collagen (Lindsedt and Prockop, 1961; Prockop, 1964; Kivirikko, Laitinen, and Lamberg, 1965). Only 5–10 per cent of the OH.P released into the circulation is excreted in the urine, the rest being oxidized to CO_2 and H_2O. Therefore, relatively large changes in the degradation of collagen are required to alter the rate of urinary excretion of OH.P which nevertheless has been found to be a useful index in a number of clinical situations. Hydroxyproline excretion is increased in several disorders of bone and several reports have indicated that it is more sensitive than other biochemical tests in conditions such as acromegaly, hyperthyroidism, and hyperparathyroidism (Jasin, Fink, Wise, and Ziff, 1962; Keiser, Gill, Sjoerdsma, and Bartter, 1964; Kivirikko, Laitinen, Aer, and Halme, 1965). Subsequent studies have shown an increased hydroxyprolinuria in patients with radiologically demonstrable metastases in bone from a variety of malignant neoplasms including carcinoma of the breast (Bonadonna, Merlino, Laird Myers, and Sonnenberg, 1966; Hosley, Taft, Oslen, Gates, and Beebe, 1966; Leroy, Carbone, and Sjoerdsma, 1966). Guzzo, Pachas, Pinals, and Krant (1969) showed that increased OH.P excretion is a more sensitive index of bone metastases than hypercalciuria. They also reported 5 patients with breast cancer and 5 patients with bronchial neoplasms in whom elevated urinary OH.P excretion predated by several months the demonstration of osseous deposits by radiography. The present study was designed to investigate the urinary excretion of OH.P in cases of breast cancer in order to assess its value as an early index of the development of osseous deposits.

MATERIAL AND METHODS

The study was performed in 18 normal females (aged 25–60 years) and 49 patients with breast cancer (aged 33–74 years). The breast cancer cases included 12 patients with radiologically demonstrable osseous deposits (group 1), 10 patients with soft-tissue deposits (group 2), 18 patients who remained free of secondary deposits throughout the period of the study (6 months to 4 years) (group 3), and 9 patients who were initially free of secondary deposits on clinical and radiological investigation but who subsequently developed osseous deposits (group 4).

All the breast cancer patients were reviewed clinically at frequent intervals and those in groups 3 and 4 had sequential urinary OH.P and creatinine excretion studies together with repeated limited skeletal surveys.

Twenty-four-hour OH.P excretion was measured in all the subjects whilst on a gelatin-free diet for 4 days. They were instructed to omit all meats, tinned fish, ice-cream, sweets, synthetic cream, jelly, lemon/orange pie fillings, cake decorations, and chocolate from their diet. Two 24-hour urine specimens were then collected on days 3 and 4 whilst still on the gelatin-free diet, using boric acid (8·0 g. per container) as a preservative. The urinary OH.P (free and total) was measured by a modification of Grant's technique (Grant, 1964). The test involves the oxidation of OH.P to pyrrole compounds which can then be used to form a specific colour reaction with *p*-dimethylaminobenzaldehyde.

The urinary creatinine was measured (standard Technicon Autoanalyser method) in order to correct for errors in the urine collection, especially in patients in whom the test was performed on an out-patient basis. Other biochemical estimations performed included serum alkaline phosphatase and fasting serum calcium (Technicon Autoanalyser).

Total OH.P and creatinine were expressed as absolute values and as an index, total OH.P/creatinine × 100, as suggested by Guzzo and others (1969).

Statistical Methods.—Student's *t*-tests for paired and unpaired data were used as appropriate. Analysis of variance was also performed on the sequential data on OH.P excretion.

RESULTS

Control Subjects.—The urinary OH.P excretion of 18 normal female adults is shown in *Table I*. No significant difference was noted between the first and the second 24-hour collections for either free or total OH.P (*Table II*). The urinary excretion of OH.P is influenced by age, and *Fig.* 1 shows the mean and S.D. of the various age-groups. It is obvious that in comparative studies the age-group of the patients and the controls should be similar.

Table I.—URINARY OH.P EXCRETION IN 18 NORMAL FEMALE SUBJECTS AGED 25–60 YEARS

	FREE OH.P (mg. per 24 hr.)	TOTAL OH.P (mg. per 24 hr.)	OH.P/CREATININE INDEX
Mean	1·87	16·6	1·73
S.D.	1·07	5·0	0·49
S.E.	0·25	1·2	0·12

Breast Cancer Patients.—The initial values for the breast cancer cases are shown in *Table III*. The total OH.P excretion and the OH.P/creatinine ratio in patients with radiologically demonstrable osseous metastases were significantly elevated when compared with the controls ($P < 0·001$). In fact the OH.P excretion was elevated in all but one of the patients in this group and the urinary OH.P excretion was a more sensitive index of osseous deposits than either the fasting serum-calcium level or serum alkaline phosphatase activity (*Fig.* 2).

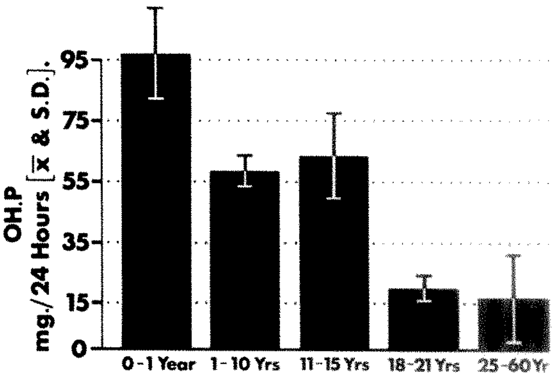

FIG. 1.—Urinary excretion of OH.P with age. Compiled from the data of Jasin and others (1962), Kivirikko and Laitinen (1965), Laitinen, Nikkila, and Kivirikko (1966), and Cuschieri and Felgate (1972).

Table II.—DIFFERENCE IN THE URINARY OH.P CONTENT BETWEEN THE FIRST AND SECOND 24-HOUR COLLECTIONS OF 17 PAIRS OF RESULTS FROM NORMAL FEMALE SUBJECTS AGED 25–60 YEARS

	FREE OH.P	TOTAL OH.P	OH.P/CREATININE INDEX
Mean difference	−0·28	0·5	0·16
S.E. of mean difference	0·14	1·0	0·11
t	1·964	0·482	1·498
P	>0·05	>0·06	>0·1

Table III.—INITIAL URINARY OH.P EXCRETION AND OH.P/CREATININE INDEX IN THE BREAST CANCER CASES STUDIED

GROUP	TOTAL OH.P (mg. per 24 hr.)	OH.P/CREATININE INDEX
1	46·0 ± 3·0*	4·70 ± 0·38*
2	26·9 ± 2·30*	2·40 ± 0·39
3	16·9 ± 2·30	2·13 ± 0·15
4	33·05 ± 6·32*	4·26 ± 0·37*

* Significant difference ($P < 0·05$) from values in a normal female population of a similar age range.

Results are expressed as mean and standard error.

In cases with soft-tissue deposits only, as assessed by clinical and radiological investigation (group 2), the urinary total OH.P excretion was significantly raised when compared with the controls ($P < 0·01$). In the patients who remained free of secondary deposits throughout the period of study the urinary excretion of OH.P fell within the normal range, whereas it was significantly elevated ($P < 0·001$) in the patients who subsequently developed radiologically demonstrable metastases between 3 and 12 months later ($P < 0·001$).

Sequential Studies.—The sequential estimations for urinary total OH.P and OH.P/creatinine index in patients who have remained free of secondary deposits to date are shown in *Table IV*. They have remained within the normal range although the total OH.P excretion has shown a significant elevation from the initial value when analysed by Student's *t*-test for paired data ($P < 0{\cdot}05$). However, analyses of variance indicated no significant change between the initial values and those at the end of 9–12 months for total OH.P excretion (F ratio = 0·633, $P > 0{\cdot}2$) and the OH.P/creatinine index (F ratio = 0·221, $P > 0{\cdot}2$).

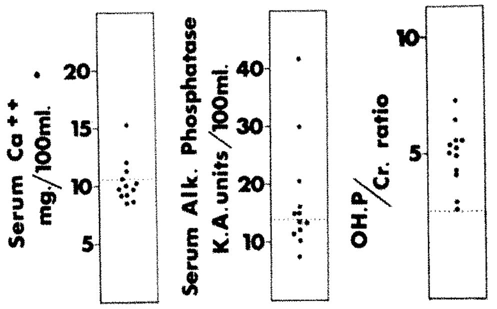

FIG. 2.—Serum-calcium and alkaline phosphatase levels and OH.P/creatinine index in 12 patients with carcinoma of the breast and osseous involvement on radiographic survey. The dotted line indicates the upper limit of the normal range.

Table IV.—SEQUENTIAL ESTIMATION OF URINARY OH.P EXCRETION AND OH.P/CREATININE INDEX (3–4 MONTHLY) IN 12 PATIENTS WHO HAVE REMAINED FREE OF SECONDARY DEPOSITS

	SEQUENTIAL ESTIMATIONS				
	1	2	3	4	*P*
Total OH.P (mg. per 24 hr.)	16·92 ± 2·27	18·28 ± 1·69	20·72 ± 2·92	20·92 ± 2·68	<0·05
OH.P/creatinine index	2·13 ± 0·15	2·06 ± 0·15	2·21 ± 0·22	2·29 ± 0·31	>0·20

Results are expressed as mean and standard error.

Table V.—SEQUENTIAL ESTIMATION OF URINARY OH.P EXCRETION AND OH.P/CREATININE INDEX (3–4 MONTHLY) IN 8 PATIENTS WHO SUBSEQUENTLY DEVELOPED RADIOLOGICALLY DEMONSTRABLE OSSEOUS METASTASES

	SEQUENTIAL ESTIMATIONS				
	1	2	3	4	*P*
Total OH.P (mg. per 24 hr.)	33·05 ± 6·32	38·21 ± 5·54	42·56 ± 7·31	42·26 ± 6·35	<0·01
OH.P/creatinine index	4·26 ± 0·37	4·49 ± 0·39	4·75 ± 0·55	4·59 ± 0·45	<0·05

Results are expressed as mean and standard error.

The sequential data for urinary OH.P excretion in patients who subsequently developed osseous deposits are shown in *Table V*. Both the total OH.P excretion and the OH.P/creatinine index have remained persistently elevated above normal and have increased significantly with time.

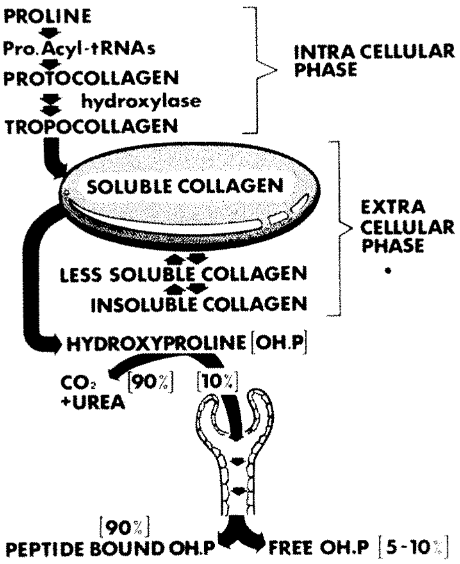

FIG. 3.—Biosynthesis and degradation of collagen.

DISCUSSION

The urinary excretion of OH.P is increased in patients with breast cancer who have radiologically demonstrable osseous deposits. Moreover, the urinary OH.P excretion was persistently elevated several months before the radiological demonstration of involvement of bone by tumour in 9 patients of the present series. It appears, therefore, that OH.P excretion is a sensitive index of secondary deposits in bone and together with radio-isotope scintiscanning is useful in accurate staging of breast cancer. The reason for increased excretion of this imino acid in the presence of secondary deposits is closely linked with the accepted scheme for the metabolism of collagen (*Fig*. 3). It appears that cells that synthesize collagen first assemble polypeptides called protocollagen which have the identical amino-acid composition of collagen except that they contain proline and lysine instead of hydroxyproline and hydroxylysine (Lukens, 1965; Juva and Prockop, 1965). An enzyme, protocollagen hydroxylase, then converts the proline and lysine to the hydroxyl compounds with the formation of tropocollagen (Kivirikko and Prockop, 1967). Thus the OH.P in the urine does not originate from OH.P peptides in precursors of collagen but results from the degradation of both newly synthetized (soluble) and to a lesser extent insoluble collagen (Prockop, 1964).

The factors known to influence OH.P excretion include age (Ziff, Kibrick, Dresner, and Cribetz, 1965), sex, growth hormone (Avioli and Prockop, 1967), and thyroid hormone (Kivirikko, Koivusalo, Laitinen, and Lamberg, 1964). The administration of moderate doses of cortisone does not affect the OH.P excretion in human subjects (Benoit, Theil, and Watten, 1963), and excretion levels in Cushing's syndrome are within the normal range (Klein and others, 1964). The administration of oestrogens to patients has been reported to decrease the urinary excretion of OH.P (Katz and Kappas, 1965). Increased OH.P excretion has been reported in various diseases affecting bone, such as Paget's disease, fibrous dysplasia, and rickets (Dull and Henneman, 1963; Crabbe and Isselbacher, 1965).

Changes in OH.P excretion are therefore not specific to a particular disease process and the finding of an elevated excretion of this imino acid in patients with breast cancer does not necessarily indicate the presence of osseous deposits. It is evident that other causes of increased hydroxyprolinuria have to be excluded on clinical and biochemical grounds. Nevertheless, it appears to be more sensitive than radiography in the detection of osseous deposits. In this respect it has been estimated by Borak (1942) that approximately 30 per cent of the bone matrix has to be destroyed before metastases become radiologically demonstrable. Our work supports Galasko's (1971) findings using radio-isotope bone scans that a significant percentage of patients with breast cancer have occult deposits in bone at the time of their initial presentation and that there is a need for reappraisal of staging in carcinoma of the breast.

Acknowledgements.—This work was carried out in association with the Department of Chemical Pathology, University of Liverpool, where the biochemical studies were performed. The author would like to thank Dr. W. Taylor, Head of the Department of Chemical Pathology, and Dr. Felgate for their close co-operation in this work.

CARDIAC SEQUELAE OF HAEMORRHAGIC SHOCK

BY C. S. McARDLE AND W. D. FISHER
UNIVERSITY DEPARTMENT OF SURGERY, WESTERN INFIRMARY, GLASGOW

SUMMARY

Using selective cardiac catheterization and a ^{133}Xe wash-out technique, myocardial blood-flow and oxygen utilization were studied in greyhounds during and following brief and prolonged haemorrhagic hypotension. The progressive fall in myocardial oxygen extraction as the shock period was prolonged and the subsequent failure of myocardial oxygen consumption to rise during re-infusion suggested the presence of a metabolic defect in the myocardial cell.

The use of a special 'elemental' diet was shown to eliminate the intestinal blood-loss typical of canine haemorrhagic shock models; despite this the apparent myocardial cellular metabolic defect persisted.

In addition, a myocardial depressant factor which depressed myocardial function *in vitro* was isolated from ultrafiltrates of post-shock plasma.

THE extent to which myocardial dysfunction contributes to death after experimental haemorrhagic shock remains uncertain. While many studies (Crowell and Guyton, 1961, 1962; Gomez and Hamilton, 1964; Siegel and Downing, 1970) have implicated the presence of overt cardiac failure, other investigators doubt whether a functional and metabolic defect occurs such that death inevitably ensues (Simeone, 1961; Weidner, Albrecht, and Clowes, 1964).

Variations in the experimental model such as the duration and severity of hypotension and the adequacy of fluid replacement during resuscitation contribute to conflicting opinion. Also many experimental studies have been performed in spontaneously breathing anaesthetized animals in which varying degrees of hypoxaemia may occur, particularly if subjected to major cardiac or thoracic surgical procedures. A particular problem in the canine haemorrhagic shock model is the occurrence of an overt haemorrhagic enteritis with secondary intraluminal blood-loss which may be massive and obscure the response to re-infusion, thus complicating the evaluation of the resuscitation phase.

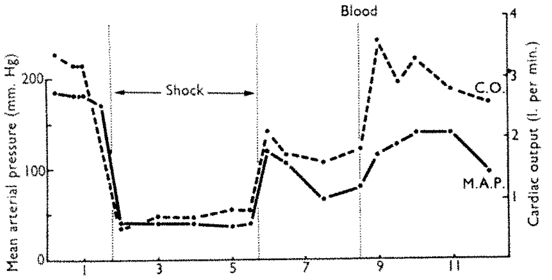

FIG. 1.—The changes in mean arterial pressure (M.A.P.) and cardiac output (C.O.) of a typical animal before, during, and after prolonged haemorrhagic hypotension (3½ hours).

The aim of the present study was therefore to evaluate the nature and severity of myocardial dysfunction following canine haemorrhagic shock using a model in which surgical manipulation was minimal, hypoxaemia did not occur, and normal blood-volumes were maintained during resuscitation, and also to assess the importance of intestinal necrosis in myocardial dysfunction. In addition, the suggestion by Lefer (1970) that cardiac failure in canine haemorrhagic shock may be due to the presence in the post-shock plasm of a circulating peptide, myocardial depressant factor (M.D.F.), which has been shown to produce depression of myocardial function both *in vitro* and *in vivo*, has been investigated further.

MATERIAL AND METHODS

Twelve anaesthetized ventilated greyhounds (weight range 23–32 kg.) were subjected to an arterial haemorrhage into a reservoir until the mean arterial pressure was 35–40 mm. Hg (Heimbach, Fisher, Hutton, McArdle, and Ledingham, 1973). In 6 animals the duration of hypotension was 210 minutes, at the end of which time the residual shed blood was re-infused. In the remaining 6 animals re-infusion was commenced after only 60 minutes. Both groups of animals were then observed for a further 4 hours.

In an attempt to eliminate the problem of intestinal blood-loss another 6 animals were fed on a special 'elemental' diet, similar to that devised by Bounous, Sutherland, McArdle, and Gurd (1967), which consisted of amino acids, carbohydrates, and fat with added salts and vitamins; the dogs were then subjected to a similar 3½-hour shock protocol.

Throughout the period of investigation recordings were made of arterial and right atrial pressure and cardiac output. Myocardial blood-flow (M.B.F.) was measured using a ^{133}Xe-clearance technique (Ross, Ueda, Lichtlen, and Rees, 1964), the xenon being injected directly into the left circumflex coronary artery via a catheter previously placed in position under fluoroscopic control. In addition, arterial, coronary sinus, and mixed venous blood-samples were withdrawn at frequent intervals for the measurement of blood-gases and other biochemical data. The oxygen content of the blood was then calculated in the following manner:—

Blood-oxygen content (ml. per 100 ml.)
= Hb (g.); measured by the cyanmethaemoglobin technique × 1·39 × percentage saturation/100 + P_{O_2} (mm. Hg) × 0·0031 (Bunsen coefficient).

It has been shown previously that within the range 7–24 ml. of oxygen per 100 ml. of blood there is a close relationship between this indirect method of measurement of oxygen content and the direct method of Van Slyke (Ledingham, McBride, Parratt, and Vance, 1970).

The following information was then obtained by calculation:—

Myocardial oxygen availability (ml. per 100 g. per min.)
= M.B.F. (ml. per 100 g. per min.) × the arterial oxygen content (ml. per 100 ml.)/100,

Myocardial oxygen extraction (per cent)
= [Coronary arterial-venous oxygen content difference (ml. per 100 ml.)/arterial oxygen content (ml. per 100 ml.)] × 100,

Myocardial oxygen consumption (ml. per 100 g. per min.)
= M.B.F. (ml. per 100 g. per min.) × [arterial oxygen content (ml. per 100 ml.) − coronary sinus oxygen content (ml. per 100 ml.)]/100.

Arterial blood samples (50 ml.) were removed prior to haemorrhage (control) and at the conclusion of each experiment (post-hypotension). Ultrafiltrates were then prepared and assayed using a guinea-pig atrial preparation (Fisher, Heimbach, McArdle, Maddern, Hutcheson, and Ledingham, 1973).

In addition, ultrafiltrates were evaporated to dryness, dissolved in a small amount of distilled water, and applied to Biogel P2 (200–400 mesh) gel chromatography columns (90 × 1·5 cm.). The columns were eluted with distilled water at room temperature and a flow-rate of 1·5–2 ml. per minute, and 3-ml. aliquots were collected and read at 230 nm. in a Unicam SP 1800 spectrophotometer. The resultant peaks were lyophylized and taken up in the original volume of Krebs-Henseleit buffer and assayed on the guinea-pig atrial preparation. Human albumin, polymyxin B (molecular weight = 1150), and tryptophan (molecular weight = 204) were used to calibrate each column.

RESULTS

The required degree of hypotension was achieved with the loss of 50 ± 3 ml. per kg. of body-weight (mean ± S.E.M.) over a 30-minute period. In the animals subjected to prolonged hypotension (3½ hours) the spontaneous re-uptake of shed blood was 39 ± 3 per cent.

The typical response to re-infusion in 1 animal subjected to prolonged (3½ hours) hypotension is shown in *Fig.* 1. The fall in mean arterial pressure and cardiac output during shock was only partly corrected upon re-infusion of the shed blood alone. Massive supplementary infusions of blood and colloid were then necessary to prevent progressive deterioration and death.

During the immediate post-infusion period there was evidence of incomplete return of normal cardiac function. Rapid re-infusion of the residual shed blood often led to disproportionately large increases in right atrial pressure, although if the rate of infusion was limited by alterations in right atrial pressure the heart was able to cope with the fluid load. Assessment of this period was further complicated by the presence of intestinal blood-loss, which at times was massive, which is a striking feature of severe and prolonged canine haemorrhagic shock.

Table I.—HAEMODYNAMIC DATA FOR ANIMALS SUBJECTED TO PROLONGED AND BRIEF HYPOTENSION

See Table I for key to abbreviations.

The haemodynamic data following both brief (1 hour) and prolonged (3½ hours) hypotension are shown in *Table I.*

With the onset of hypotension there was a significant increase in heart-rate ($P < 0{\cdot}001$) and the stroke volume fell by 80 per cent. In resuscitation despite re-infusion of the residual shed blood along with additional fluid the mean arterial pressure remained significantly below control values ($P < 0{\cdot}001$) although the right atrial pressures were normal. By the end of the resuscitation, however, cardiac output and myocardial blood-flow had returned to levels not significantly different from the control values. Random left ventricular end diastolic pressures were normal. In contrast, after only 1 hour's hypotension re-infusion of the residual shed blood rapidly restored these parameters to within normal limits.

With the onset of hypotension there was a slight fall in arterial oxygen tension which quickly corrected itself in resuscitation. In the presence of an unchanged minute ventilation and inspired oxygen concentration this indicates that significant alveolar hypoventilation did not occur. Arterial *p*H fell substantially early in shock to a mean of 7·18 ± 0·02 units but did not deteriorate further even after 3½ hours' hypotension. The *p*H remained low during early resuscitation but by the end of the experiment had returned to control values without the addition of alkaline fluids. These changes in *p*H were predominantly related to a gross metabolic acidosis, the mean base excess falling to − 15 ± 1 mEq./l. during hypotension.

The changes in myocardial oxygen usage following both brief and prolonged hypotension are shown in *Table II.* The changes in myocardial oxygen availability reflect the changes in myocardial blood-flow, there being no significant change in arterial oxygen content between the control and resuscitation phases. Concomitant with the fall in myocardial blood-flow in shock there was a significant rise in myocardial oxygen extraction ($P < 0{\cdot}001$). However, as the period of hypotension was prolonged myocardial oxygen extraction fell despite no further alteration in myocardial oxygen availability. In addition, myocardial oxygen consumption which fell by 65 per cent in shock failed to rise significantly above shock levels in resuscitation, thereby suggesting the presence of a metabolic defect in the myocardial cell. By contrast, in the animals subjected to only brief hypotension myocardial oxygen extraction and consumption rapidly returned to normal values, thus showing that the changes seen after prolonged hypotension are not solely related to a non-specific deterioration in the preparation used.

'Elemental' Diet.—A number of important differences emerged in the group of animals fed on the 'elemental' diet and then subjected to prolonged shock.

In the initial or control group of animals subjected to prolonged hypotension the early period of resuscitation was bedevilled by the occurrence of multiple arrhythmias associated with profound falls in the mean arterial pressure and cardiac output.

A–V junctional rhythms predominated although supraventricular tachycardias with left bundle branch block and atrial fibrillation also occurred. By contrast arrhythmias in the 'elemental' diet-fed animals were transient and not associated with hypotension.

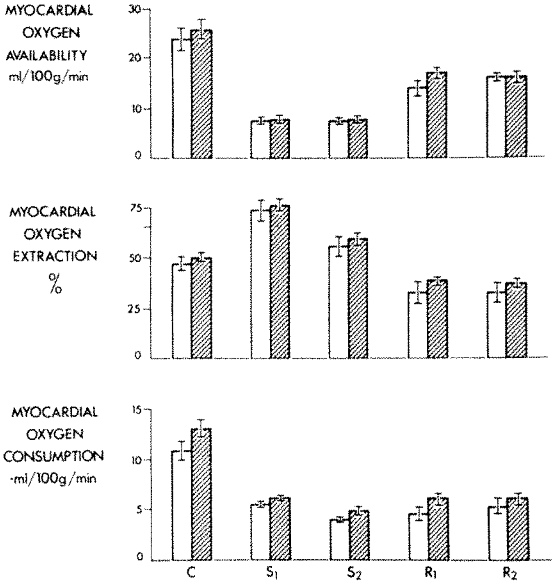

FIG. 2.—Myocardial oxygen availability, extraction, and consumption following prolonged haemorrhagic hypotension (3½ hours) in control (open columns) and 'elemental'-diet-fed (shaded columns) animals (mean ± S.E.M.).

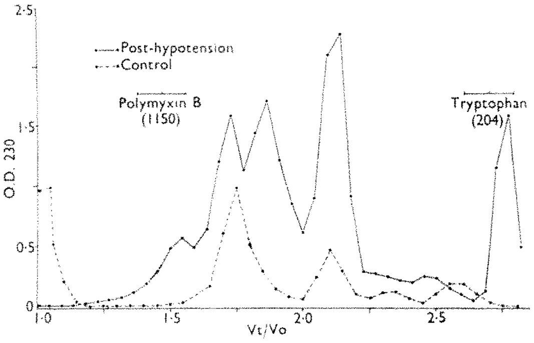

FIG. 4.—Elution curves of 5-ml. samples of ultrafiltrates from an animal before and after 3½ hours' hypotension following application to a Biogel P_2 column. Vt/Vo, Total eluted volume/void volume of column. The positions of the peaks of the markers of known molecular weight are shown.

The spontaneous re-uptake of shed blood during shock was only 16 ± 3 per cent in the 'elemental'-diet-fed animals as opposed to 39 ± 3 per cent in the control animals. In addition, 'elemental'-diet-fed animals required only a mean additional 12 ml. per kg. of body-weight of whole blood or colloid to maintain their haemodynamic parameters in resuscitation, as opposed to a mean additional 56 ml. per kg. of body-weight required by the control animals.

The explanation for these findings was seen on post-mortem examination of the gut, which in the 'elemental'-diet-fed animals was macroscopically normal, in contrast to the gross haemorrhagic enteritis in the control animals.

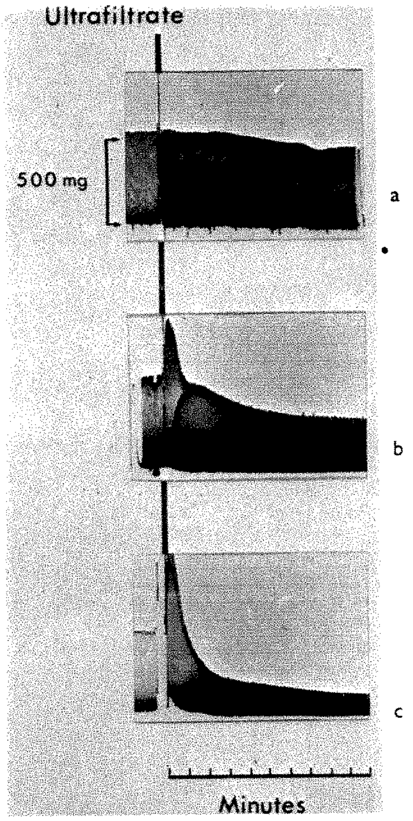

FIG. 3.—Typical tracings of guinea-pig atrial activity following the addition of ultrafiltrates from (a) control pre-shock, (b) brief hypotension (1 hour), and (c) prolonged hypotension (3½ hours) plasma.

However, in spite of the improved stability in the immediate post-infusion period and the elimination of the need for massive quantities of additional fluid in resuscitation there was no significant improvement in myocardial oxygen extraction or myocardial oxygen consumption, as seen in *Fig*. 2. It is therefore unlikely that the defect in myocardial oxygen usage seen in resuscitation is related to the presence of intestinal mucosal necrosis with secondary intraluminal blood-loss.

M.D.F.—Typical tracings produced by ultrafiltrates obtained from individual animals during the control period and following brief and prolonged hypotension in undieted animals are shown in *Fig*. 3. Following the addition of ultrafiltrates the initial increase in developed tension is the result of temporary exposure of the atrium on emptying the organ bath.

Control samples produced 15 ± 2 per cent (mean ± S.E.M.) depression. Following 1 hour of hypotension depression had increased significantly ($P < 0{\cdot}001$) to 45 ± 4 per cent, and after 3½ hours' hypotension had increased significantly further ($P < 0{\cdot}005$) to 77 ± 9 per cent.

Following 3½ hours' hypotension there was no significant difference in percentage depression between the control dogs and those fed on the special elemental diet (73 ± 4 per cent).

Typical elution patterns of ultrafiltrates obtained in the control period and after 3½ hours' hypotension are shown in *Fig.* 4. Significant depression was found to occur in the fourth peak ($Vt/Vo = 2{\cdot}1$) after 3½ hours' hypotension. In 4 dogs this peak produced a mean depression of 54 ± 10 per cent. This peak would correspond to a substance with a molecular weight of 500–700. The remaining peaks produced little depressant activity.

DISCUSSION

These studies have shown that following severe and prolonged canine haemorrhagic shock, progressive cardiac failure need not occur. Indeed, with careful and appropriate fluid replacement cardiac output may return to within normal limits.

Nevertheless, the progressive decrease in myocardial oxygen extraction and consumption with prolongation of hypotension and in the presence of an unchanged myocardial oxygen availability would suggest a metabolic defect in the myocardial cell. A similar deterioration in myocardial performance has been noted by others (Crowell and Guyton, 1961, 1962; Gomez and Hamilton, 1964; Regan, La Force, Teres, Block, and Hellems, 1965).

The defect in oxygen utilization is unlikely to be related to an increase in preferential blood-flow through the myocardium, as nutritive flow (as measured by the xenon-flow technique) does not change as the period of hypotension is prolonged. Alternatively the decrease in oxygen extraction might be due to a transfer to anaerobic pathways in the myocardial cell. However, previous studies from this laboratory (Heimbach and others, 1973) and others (Edwards, Siegel, and Bing, 1954; Lundsgaard-Hansen, 1966) have shown that this does not occur. Furthermore, in resuscitation myocardial oxygen consumption fails to rise despite an increased myocardial oxygen availability, and this would further support the concept that the defect lies in the inability of the myocardial cell itself to extract oxygen.

The assessment of the resuscitation period following severe canine haemorrhagic shock is complicated by the presence of intestinal necrosis with secondary intraluminal blood-loss and the consequent instability of the model. It has been shown that this problem can be eliminated by the simple expedient of pretreating the animal with a special elemental diet.

Despite the improved stability of the model and the elimination of the need for massive quantities of fluid in resuscitation there was no significant improvement in myocardial extraction or consumption, suggesting that the defect in myocardial cellular metabolism is not related to the presence of toxic substances released from the 'shocked' gut.

The presence in the post-shock plasma of a circulating substance of low molecular weight which can produce depression of myocardial contractility *in vitro* is intriguing. It is interesting to note that it appears in association with the deterioration in cardiac function and its appearance may contribute to the development of the myocardial metabolic cellular defect. As there is no significant difference in the degree of depression obtained with ultrafiltrates from animals with or without intestinal necrosis it is unlikely that this depressant factor is related to the toxic breakdown substances produced in the 'shocked' intestine. Partial purification by gel chromatography would suggest that the active component is a single compound with a molecular weight of 500–700.

EARLY CHANGES IN THE POST-PHLEBITIC LIMB: THEIR CLINICAL SIGNIFICANCE

By T. P. CORRIGAN and V. V. KAKKAR

DEPARTMENT OF SURGERY, KING'S COLLEGE HOSPITAL MEDICAL SCHOOL, LONDON

SUMMARY

The long-term results of treatment of the established post-phlebitic syndrome by compression sclerotherapy or by ligation of incompetent perforating veins were unsatisfactory in approximately 40 per cent of patients. Changes in superficial venous pressure during exercise occurred when the deep veins were recanalized and the perforating veins became incompetent. These pressure changes could be used to select patients likely to develop the full syndrome. It is suggested that development of an intractable syndrome might be prevented if ligation of incompetent perforating and deep veins is performed before tissue changes become established.

DEEP-VEIN thrombosis is an important cause of disability and death. The patient may die from pulmonary embolism or may develop the post-phlebitic syndrome which represents one of the common and intractable problems in surgery.

When thrombosed veins recanalize the valves are destroyed (Edwards and Edwards, 1937) and become incompetent, causing sustained high pressure in the leg veins (Beecher, 1937; Linton and Hardy, 1948). The patients complain of pain in the leg, swelling, eczema, pigmentation, and ulceration. Several workers have stressed that incompetent perforating veins are responsible for these clinical features (Homans, 1917; Linton, 1938; Cockett and Elgan Jones, 1953; Fegan, 1967). This concept has been the basis for treating these patients by ligation of incompetent perforating veins (Cockett and Elgan Jones, 1953) or by compression sclerotherapy (Fegan, 1963).

In this paper we report the results of a study which had two aims: first, to compare the effectiveness of subfascial ligation and compression sclerotherapy in treating patients with the post-phlebitic syndrome, and secondly to define criteria which could be used to select patients likely to develop severe disease so that treatment could be instituted at an early stage before an intractable syndrome develops.

MATERIAL AND METHODS

The present study was conducted in two parts.

1. Assessment of Treatment.—

Patients.—Eighty patients were studied; their age, sex, and presenting clinical features are shown in *Table I*. Incompetent perforating veins (*Fig.* 1) were located by ascending phlebography (Kakkar, 1972). The patients were also examined for incompetence of the saphenofemoral or saphenopopliteal valves. Patients who had ulceration or marked oedema were admitted to hospital. The ulcers were healed and the oedema was controlled before commencing the selected treatment. Envelopes were prepared, sealed, and numbered in sequence, each containing one of two treatment schedules in random order. As each patient was admitted to the trial his treatment was selected by opening the next envelope.

Compression Sclerotherapy.—The technique of sclerotherapy employed was that described by Fegan (1967); 0·5–1·0 ml. of sodium tetradecyl (S.T.D.) was injected through a 21-gauge needle into each of the sites which had been shown by phlebography to be that of an incompetent perforating vein. In patients with saphenofemoral or saphenopopliteal incompetence the saphenous vein was ligated at its junction with the main vein before commencing compression sclerotherapy.

Table I.—AGE, SEX, AND PRESENTING CLINICAL FEATURES IN 80 PATIENTS WITH THE POST-PHLEBITIC SYNDROME

	TREATMENT	
	Compression Sclerotherapy	Ligation of Incompetent Perforating Veins
No. of patients	43	37
Age		
Range (yr.)	28–70	34–68
Mean	42	47
Male : female ratio	10 : 33	14 : 23
Previous surgery	11	8
Clinical features		
Aching pain	34	29
Ankle oedema	20	15
Eczema	24	17
Pigmentation	36	29
Induration	33	25
Varicose veins	19	12
Ulcers	31	24
Saphenofemoral or saphenopopliteal incompetence	11	6

Ligation of Incompetent Veins.—Patients in this group were admitted to hospital. The sites where phlebography had shown perforating veins were explored under general anaesthesia and the veins were ligated subfascially. If a tortuous vein was found during dissection it was ligated and excised. Incompetence at the saphenofemoral or saphenopopliteal junction was dealt with in exactly the same manner as described above.

Aftercare and Follow-up.—Patients in both groups were seen in the Varicose Veins Clinic at regular intervals. Aftercare was similar in both groups; all the patients wore elastic stockings for a period of at least 3 months.

2. Assessment of Early Changes.—

Patients.—Thirty patients who had developed acute extensive deep-vein thrombosis which had been treated by us during the preceding 4 years were investigated. In each case phlebograms had been performed to confirm the diagnosis and had been repeated to assess the final outcome. The patients had been treated with heparin for 7 days followed by oral anticoagulants for 6–9 months. In 16 patients the tibial, popliteal, and femoral veins had been involved while in 14 cases the thrombus had extended into the iliac segment as well (*Table II*).

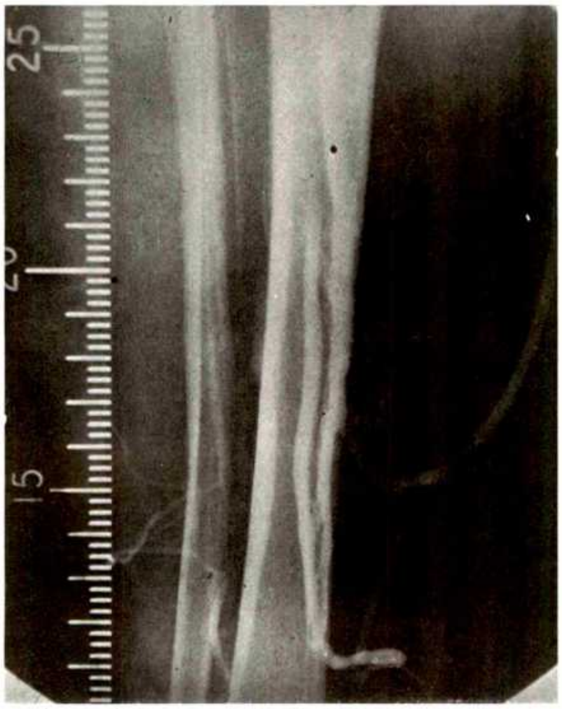

FIG. 1.—Phlebogram showing the tibial vein and two incompetent perforating veins. A radio-opaque ruler marks the distance in centimetres from the tip of the lateral malleolus.

Table II.—TIME INTERVAL BETWEEN EPISODE OF DEEP-VEIN THROMBOSIS AND THE PRESENT INVESTIGATION

Time after Deep-vein Thrombosis (mth.)	*No. of Patients*
6	8
12	14
24	4
36	2
48	2

In 20 patients the normal limb was also investigated on the present occasion. A total of 50 legs were therefore examined and the following investigations were performed.

Ascending Functional Cine-phlebography.—Patency of the deep veins, sites of incompetent perforating veins, and the function of their valves were studied. The technique of phlebography employed has already been described in detail (Kakkar, Howe, Laws, and Flanc, 1969).

Pressure Studies.—Pressure in the superficial veins was recorded in each patient. A scalp vein infusion needle attached to a flexible polyethylene tube was introduced into a vein on the dorsum of the foot. The cannula was connected to a Bell & Howell pressure transducer, type 4-327-L221, with a recording range of 0–75 cm. Hg, connected to a Devices pen recorder. The patients were examined in a standing position. The pressure was allowed to stabilize while the patient stood 'at ease'. He was then instructed to walk 'in place' for a period of 30 seconds and at the end of this time he stood 'at ease' until the pressure stabilized again. This was repeated three times.

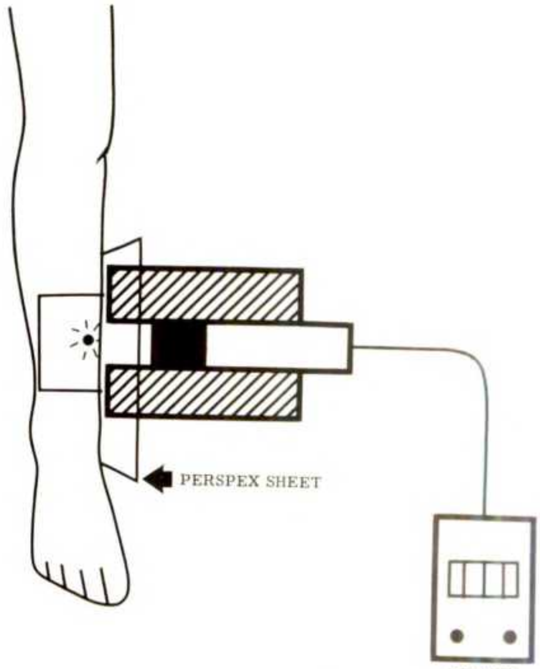

FIG. 2.—^{24}Na clearance was measured from a site approximately 5 cm. above the medial malleolus. The ^{24}Na depot was maintained in constant relation to the collimator by the Perspex sheets shown.

The following pressure measurements were analysed in each tracing: pressure in an upright position at rest (resting pressure); pressure immediately after a period of walking 'in place' (end exercise pressure); time taken for the pressure to return to the resting level after exercise (return time).

Sodium (^{24}Na) *Clearance.*—Venous flow-rate and capillary permeability were assessed by measuring ^{24}Na clearance from the subcutaneous tissues in the ankle region. The investigations were performed in a room where the temperature was maintained at between 25 and 27° C. The patient rested in a horizontal position on a couch for 15 minutes before the examination began. A site approximately 5 cm. above the medial malleolus was marked with a skin pencil and 0·05 ml. of isotonic saline containing 2·5 μc. of ^{24}Na was injected into the subcutaneous tissue, using a fine-bore (25G) needle. Ten minutes after the injection the patient was allowed to stand up and the radioactivity directly over the injected site was recorded (*Fig.* 2). The radioactivity was measured with a scintillation counter, the counts being recorded for a 10-second period in each minute for 5 minutes. The patient was then allowed to walk 'in place' for exactly 50 seconds and at the end of this period the radioactivity was recorded again in the same manner. This was repeated four times so that the patient was exercised for a total of 5 minutes. Great care was taken to ensure that all readings were obtained from the same area by placing the limb in exactly the same position in relation to the scintillation probe on each occasion.

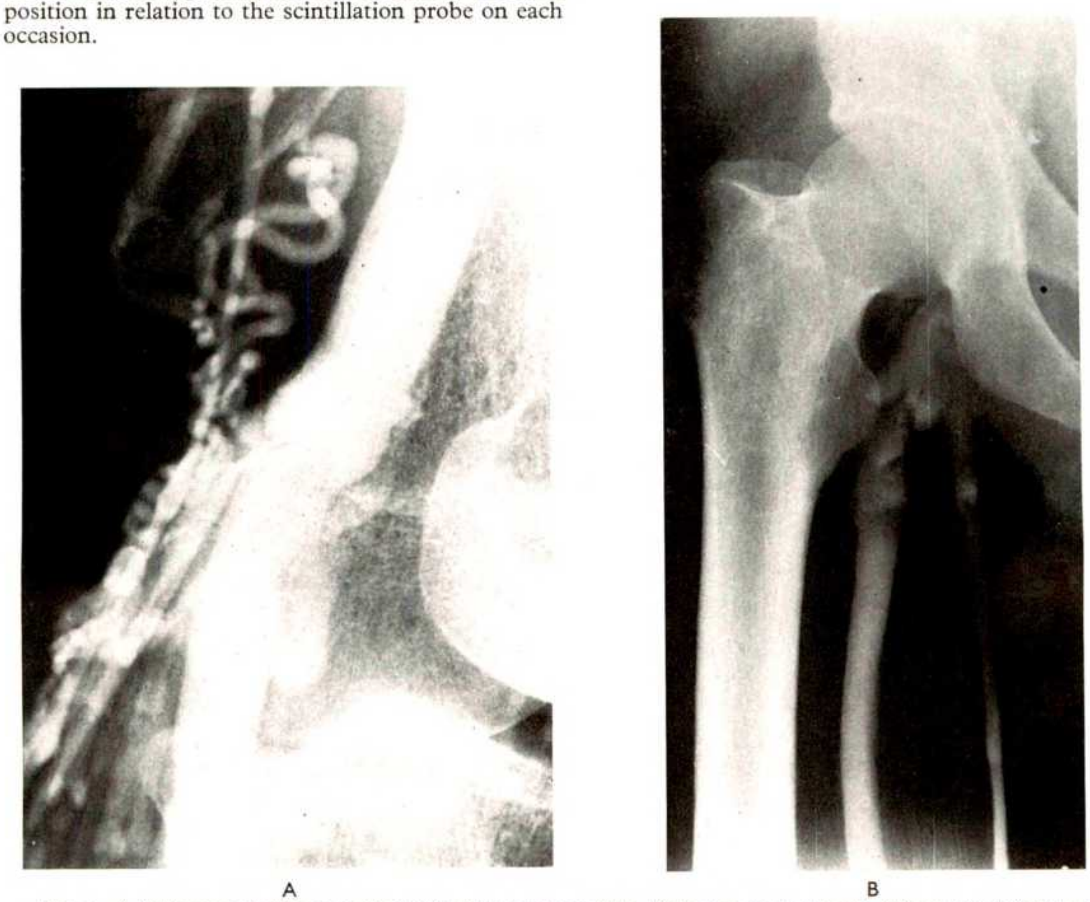

FIG. 3.—A, Phlebogram showing the popliteal vein and a competent valve. Both cusps are clearly seen. These opened with the onward flow of blood and closed during the Valsalva manœuvre. B, Phlebogram showing the femoral and long saphenous veins. Both cusps are clearly seen. The valve was found to be competent.

Electron Microscopy.—The ultrastructure of the subdermal capillaries, venules, and superficial veins was examined in 7 early post-phlebitic limbs and 3 normal limbs. The biopsies of subdermal tissue and subcutaneous veins were obtained under local or general anaesthesia. The tissues were fixed in isotonic 1 per cent osmium tetroxide and after standard processing sections were cut on an LKB ultratome. These sections were examined with an AEI electron microscope.

RESULTS

1. Assessment of Treatment.—Of the 80 patients treated, 5 died from various causes and another 8 failed to attend the clinic or moved to other areas. These patients were excluded from further consideration. This left 67 patients for analysis and all have been followed up for a period of at least 3 years. Of these, 38 patients had compression sclerotherapy and in the remaining 29 patients the incompetent perforating veins were ligated.

Table III.—RESULTS OF COMPRESSION SCLEROTHERAPY AND LIGATION OF INCOMPETENT PERFORATING VEINS (I.P.V.) ASSESSED AT 3 MONTHS, AND 1 AND 3 YEARS

DURATION OF FOLLOW-UP	COMPRESSION SCLEROTHERAPY (38 Patients)				LIGATION OF I.P.V.'s (29 Patients)			
	Satisfactory		*Un-satisfactory*		*Satisfactory*		*Un-satisfactory*	
	No.	Per cent	No.	Per cent	No.	Per cent	No.	Per cent
3 months	37	88	7	12	22	75	7	25
1 year	25	62	13	38	20	70	9	30
3 years	21	57	17	43	18	65	11	35

The results were recorded as satisfactory when the patient remained asymptomatic throughout the period of follow-up and did not develop further skin changes, and if the stasis ulcer which had been present before treatment remained healed. All other patients were classified as having unsatisfactory results.

Three months after completion of treatment 31 patients (88 per cent) in the compression sclerotherapy group and 22 (75 per cent) in the ligation group had satisfactory results. However, an increasing number of patients developed a recurrence of symptoms or ulceration during the follow-up period (*Table III*). At the end of 3 years 43 per cent of patients in the compression sclerotherapy group and 35 per cent in the ligation group had unsatisfactory results.

In normal limbs the mean return time was 45 seconds. In patients who had blocked deep veins but competent perforators the return time was also 45 seconds. However, in patients with recanalized or blocked veins but with incompetent perforators the return time was considerably less (*Table IV*, *Fig.* 5).

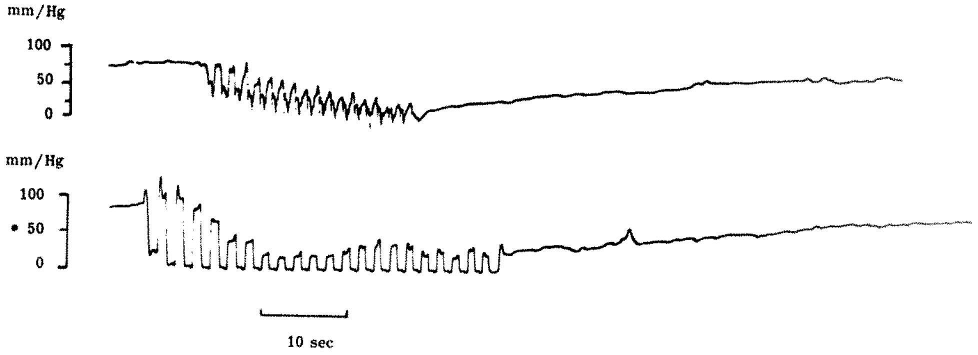

FIG. 4.—Pressure tracing in the normal (*above*) and early post-phlebitic limb (*below*) of the same patient. The resting pressure in the normal limb is 75 mm. Hg; during exercise the pressure fell to 20 mm. Hg and returned to the resting level in 45 seconds. A similar pattern is seen in the other limb. Phlebography in this limb showed blocked femoral and competent perforating veins.

Table IV.—PHLEBOGRAPHIC FINDINGS AND SUPERFICIAL VENOUS PRESSURE IN 20 NORMAL AND 30 POST-PHLEBITIC LIMBS

PHLEBOGRAPHIC FINDINGS	NO. OF LIMBS	MEAN RESTING PRESSURE (mm. Hg)	MEAN END EXERCISE PRESSURE (mm. Hg)	MEAN RETURN TIME (sec.)
Normal limbs	20	85 (75–95)	16 (5–25)	45 (24–80)
Deep veins blocked, perforating veins competent	16	80 (75–85)	20 (15–25)	45 (25–60)
Deep veins blocked, perforating veins incompetent	8	80 (75–90)	25 (20–30)	15 (10–18)
Deep veins incompetent, perforating veins incompetent	6	80 (75–95)	56 (50–80)	8 (0–18)

Figures in parentheses represent the range.

2. Assessment of Early Changes.—In the second part of the study 50 limbs were examined.

Phlebography.—It was possible to classify the state of the deep veins into four groups on the basis of the phlebographic findings (*Table IV*). The function of the valves in the venous system was also assessed. A valve was considered to be competent when both cusps were seen to open and close with onward flow of blood and no retrograde flow occurred (*Fig.* 3). In normal limbs the tibial and popliteal valves were invariably found to be competent. However, the upper femoral valves could not be seen consistently. Six patients had recanalized veins and in none of these could valves be demonstrated.

Pressure Studies.—There was no difference in the resting pressure between normal limbs and those with blocked or recanalized deep veins (*Table IV*). The end exercise pressure in normal limbs and in those with blocked veins was also similar (*Fig.* 4), but was considerably higher in those with recanalized veins (*Table IV*).

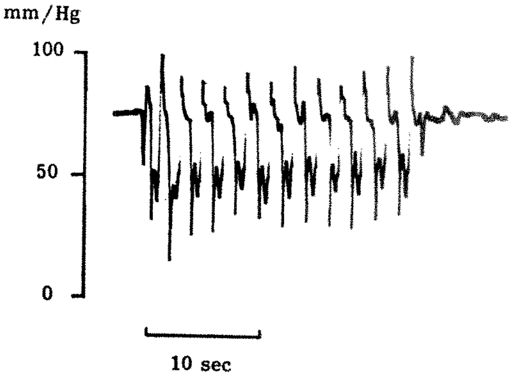

FIG. 5.—Pressure tracings in an early post-phlebitic limb. The resting pressure is 80 mm. Hg; after exercise the pressure immediately returned to the resting level. Phlebography in this limb showed recanalized deep veins and incompetent perforating veins.

^{24}Na *Clearance*.—The counts recorded during rest and during exercise were analysed by a Digital Equipment Corporation PDP-8 computer and clearance slopes were obtained (*Fig.* 6). In normal limbs the mean clearance rate per minute at rest was 0·73 per cent and during exercise this increased to 2·6 per cent per minute. In patients with blocked or recanalized veins the mean clearance rate at rest was 0·59 per cent per minute and during exercise 1·7 per cent per minute. Comparing these two groups, the clearance rates at rest were similar (*Fig.* 7) but during exercise clearance was more rapid in normal limbs than in those with blocked or recanalized veins; this difference was statistically significant ($P < 0{\cdot}02$).

Electron Microscopy.—The structure of the capillaries and subcutaneous veins was studied. The tissues obtained from the normal limbs showed that the capillaries consisted of a single layer of epithelial cells and occasional pericytes surrounded by a basement membrane. The endothelial cell cytoplasm was flattened and fenestrations were observed in some areas. In the venules of approximately 50–80 μ in diameter the endothelial cells were surrounded by a complete layer of pericytes, a basement membrane, and a connective-tissue sheath made up of bundles of collagenous fibrils and veil cells.

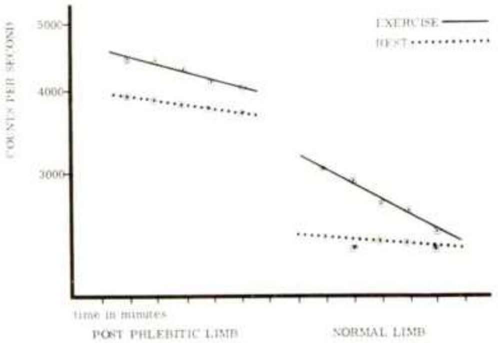

FIG. 6.—Sodium clearance from the subcutaneous tissue in the normal limb and early post-phlebitic limb of the same patient. The clearance rate on exercise in the normal limb is 5·0 per cent per minute and in the post-phlebitic limb 2·8 per cent per minute.

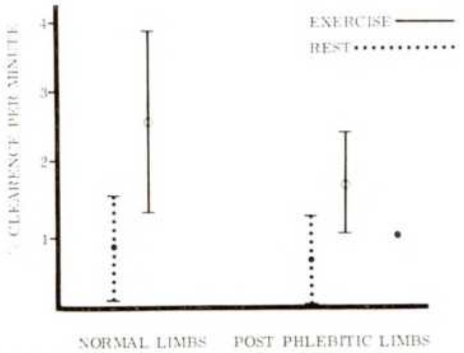

FIG. 7.—The mean and standard deviation of sodium clearance in 20 normal and 22 post-phlebitic limbs. The exercise clearance is significantly reduced in the post-phlebitic group ($P < 0{\cdot}02$).

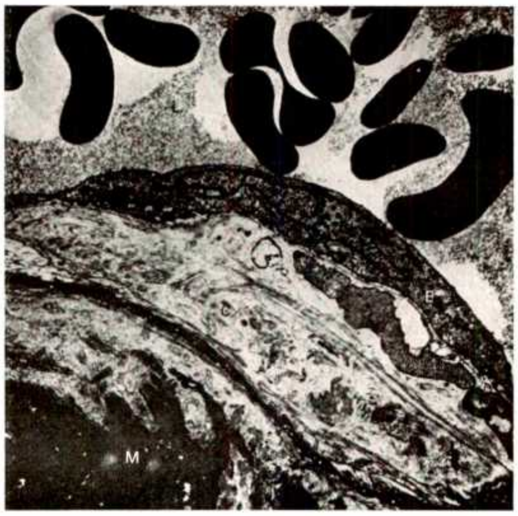

FIG. 8.—Electron micrograph of a subdermal vein obtained from a normal limb. In the lumen (L) many red-blood cells are seen. The epithelial cell (E) is flattened and has a regular surface. The basement membrane has a uniform surface. A layer of collagenous fibrils (C) underlying the basement membrane is seen. A muscle cell (M) is also present. (× 8250.)

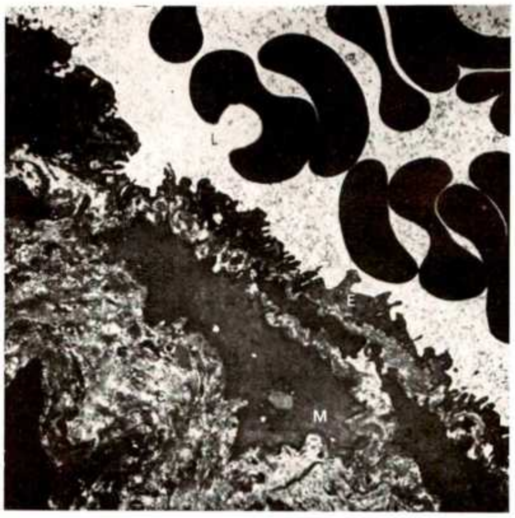

FIG. 9.—Electron micrograph of a subdermal vein obtained from a post-phlebitic limb. In the lumen (L) red-blood cells are again seen. The epithelial cells (E) are disorganized and have multiple cytoplasmic projections into the lumen. The basement membrane is thickened in some areas. The smooth muscle cells (M) and the collagenous fibrils (C) show similar changes. (× 8250.)

Sections of capillaries and venules from post-phlebitic limbs showed that the endothelial cells were often swollen and contained large vacuoles and cytoplasmic projections into the lumen of the vessel. The basement membrane was thickened in places but this change was not uniformly observed (*Figs.* 8, 9).

DISCUSSION

The management of patients with the post-phlebitic syndrome presents a major clinical problem. Treatment of incompetent perforating veins fails to produce satisfactory results in all patients. This study has shown that when localized perforating veins are blocked by ligation or by compression sclerotherapy, long-term satisfactory results are obtained in only 60 per cent of patients.

These findings raise two important questions: why does treatment fail in approximately 40 per cent of patients, and, secondly, what can be done to improve these results? Failure of treatment may be due to several factors. It is possible that some of the incompetent perforating veins were missed during treatment in this study. However, this is unlikely since our findings (Kakkar, Howe, and Flanc, 1969) and those of others (Townsend, Jones, and Williams, 1967) have shown that phlebography is an accurate method of localizing these veins.

Another possibility is that in patients where treatment fails incompetence of the deep venous system plays a major role in the production of symptoms rather than the incompetent perforating veins. If this is true it is not surprising that treatment directed towards dealing with incompetent perforating veins alone fails in a high proportion of patients.

Thirdly, it is possible that irreversible tissue changes may have already occurred in some patients and correction of the haemodynamic abnormality at this stage fails to improve their symptoms.

What can be done to improve the results? Several workers (Bauer, 1948; Linton and Hardy, 1948) have stressed the importance of deep venous incompetence. Procedures suggested to deal with this abnormality include popliteal vein resection (Bauer, 1948), ligation of the superficial femoral vein distal to the junction with the deep femoral vein (Linton and Hardy, 1948), venous by-pass grafting (Hardin, 1962), or the formation of an artificial popliteal valve by transposition of the gracilis tendon (Psathakis, 1966). Although these methods have been claimed by their proponents to be successful they have not met with general acceptance and their multiplicity in itself suggests that the results do not justify their use in patients with the post-phlebitic syndrome.

Another approach would be to select at an early stage the patients who are likely to develop a severe degree of the post-phlebitic syndrome and to initiate treatment before secondary tissue changes developed. In order to select these patients we have assessed the value of pressure measurements in the superficial veins and ^{24}Na clearance to determine the venous flow-rate and capillary permeability. These factors have been investigated because it is believed that sustained venous hypertension (De Camp, Schramel, Ray, Feibleman, Ward, and Ochsner, 1951) and abnormal capillary permeability and venous flow-rate (Fontaine, 1957) are basic mechanisms involved in the pathogenesis of the post-phlebitic syndrome. ^{24}Na-clearance studies showed that although there were differences between normal and early post-phlebitic limbs during exercise, suggesting an impaired capillary permeability and blood-flow in the latter, a considerable overlap was observed when individual patients in each group were compared. The degree of scatter observed in our studies was similar to that reported by McInally, Campbell, Robertson, and Douglas (1952). It is therefore unlikely that this investigation would in itself be useful in patient selection.

The measurement of pressure in the superficial veins was found to be the most useful indicator of future trouble. In patients with blocked veins and competent perforators as shown by phlebography, the pressure pattern was similar to that found in normal limbs, suggesting that venous return is maintained via a competent collateral circulation. Patients with blocked deep and incompetent perforating veins had a pressure pattern which differed from the normal but the differences were not clear-cut. However, those with recanalized deep veins and incompetent perforating veins had a high end exercise pressure and a very short return time. This change is similar to that seen in patients with a well-established post-phlebitic syndrome (Warren, White, and Belcher, 1949; De Camp and others, 1961; Arnoldi, 1966). It can therefore be argued that the development of an intractable syndrome can be prevented if ligation of incompetent perforating and deep veins is performed at the time that these pressure changes occur.

Acknowledgements.—We wish to thank Professor J. G. Murray and Mr. C. T. Howe for their help and encouragement and for allowing us to study their patients; Pfizer Ltd. (U.K.) for financing a research fellowship for T. P. C.; Dr. Ferrigan, Department of Pathology, Pfizer Ltd., Sandwich, Kent, for help in preparing and examining electron microscopic sections; Dr. M. B. Clarke for computer assistance; Mr. K. Eley for technical help; Mr. Redman, Royal College of Surgeons of England, for the photographs; and Mrs. Margaret Shelton for secretarial help.

THE INTESTINAL COMPLICATIONS OF RADIOTHERAPY

By J. M. WELLWOOD and B. T. JACKSON
ST. THOMAS'S HOSPITAL, LONDON

SUMMARY

The clinical features of 38 patients with intestinal complications after radiotherapy are recorded. Intestinal complications are commonly progressive and in this series led to the death of 14 patients (37 per cent). Nine of these patients had no sign of recurrent tumour. 'Spontaneous' necrosis of the irradiated bowel and necrosis of intestinal anastomoses after surgical operation carried a particularly high mortality. Only 3 patients (8 per cent) became completely asymptomatic after treatment of their bowel disease. Apparently localized radiation lesions in the small bowel were sometimes associated with severe malabsorption. Radiographs showed distinctive radiological patterns in the small bowel. A combined radiotherapy/surgical follow-up clinic is advocated.

DIARRHOEA and systemic upset commonly occur during or shortly after pelvic radiotherapy. These acute symptoms usually subside but they may sometimes be replaced by symptoms of chronic intestinal damage. These intestinal complications of radiotherapy have received little attention in the British literature although sporadic reports have appeared in North America and the Continent (Graham and Villalba, 1963; Calame and Wallach, 1967; Smith, Douglas, McLean, Ruckley, and Bruce, 1968; DeCosse, Rhodes, Wentz, Reagan, Dworden, and Holden, 1969; Lindahl, 1970; Yuen and Boyes, 1970). This paper presents the clinical features of 38 patients with chronic radiation damage to the bowel who attended St. Thomas's Hospital, London, between 1961 and 1971 inclusive.

Table I.—ORIGINAL DISEASES TREATED BY RADIOTHERAPY AND THE INCIDENCE OF INTESTINAL COMPLICATIONS AT ST. THOMAS'S HOSPITAL DURING THE YEARS 1961–71

ORIGINAL DISEASE TREATED BY RADICAL RADIOTHERAPY	NO. OF PATIENTS DEVELOPING INTESTINAL COMPLICATIONS	INCIDENCE OF INTESTINAL COMPLICATIONS (per cent)
Carcinoma of cervix	17	7
Carcinoma of bladder	13	9
Carcinoma of endometrium	2	2
Carcinoma of ovary	2	4
Carcinoma of prostate	2	4
Seminoma of testis	1	—
Menorrhagia	1	—

CLINICAL FINDINGS

There were 26 women and 12 men in the series, their ages ranging from 39 to 76 years at the time of presentation with intestinal symptoms. All except 1 patient had received radiotherapy for malignant disease (*Table I*). Eleven patients (29 per cent) had received what would now be regarded as a high or in some cases very high dose of radiation during the development of a new dose fractionation technique for use with hyperbaric oxygen. Twenty-five patients had large-bowel complications (*Table II*) and 21 had small-bowel complications (*Table III*). Seventy per cent had more than one complication. The incidence of pre-radiotherapy operations or pelvic sepsis was 32 per cent. This incidence was the same in the group of patients with large-bowel complications and in the group with small-bowel complications.

Table II.—LARGE-BOWEL COMPLICATIONS OF RADIOTHERAPY IN 25 PATIENTS

Complication	*No. of Patients*
Proctocolitis	18
Stricture	
Colorectal	13
Anal	4
Rectal ulcer	7
'Spontaneous' necrosis	3
Fistula	3

Table III.—SMALL-BOWEL COMPLICATIONS OF RADIOTHERAPY IN 21 PATIENTS

Complication	*No. of Patients*
Stricture	11
Malabsorption	9
'Spontaneous' necrosis	6
Fistula	2
Impaired healing	6

Table IV.—TIME INTERVALS BETWEEN COMPLETION OF RADIOTHERAPY AND THE DEVELOPMENT OF SYMPTOMS OF LARGE-BOWEL COMPLICATIONS

COMPLICATION	NO. OF PATIENTS	TIME INTERVALS			
		<6 mth.	<1 yr.	1–5 yr.	>5 yr.
Proctocolitis or rectal ulcer	25	13	8	3	1
Colorectal stricture	13	5	5	2	1
Anal stricture or spontaneous necrosis or fistula	10	0	3	4	3

Five of the patients (13 per cent) had clinical evidence of arteriosclerosis.

There was a latent interval between completion of radiotherapy and the development of intestinal complications (*Tables IV, V*). Proctocolitis, rectal ulcers, and steatorrhoea tended to occur earlier than large- and small-bowel stricture formation. Perforations, fistulae, and anal strictures were relatively late complications. Commonly, one intestinal complication was the precursor of another and the disease was often progressive. Proctocolitis preceded the development of colorectal strictures by up to a year and antedated anal strictures by up to 4½ years. Colorectal stricture was associated with subsequent perforation of the rectum in one patient and with the later development of a rectovesical fistula in another. Abdominal pains had been present for between 1 week and 20 months before the emergency admission of 4 of the 6 patients with spontaneous necrosis of the small bowel. Large-bowel complications had caused severe symptoms in the other 2 patients with small-bowel necrosis and may have masked small-bowel symptoms.

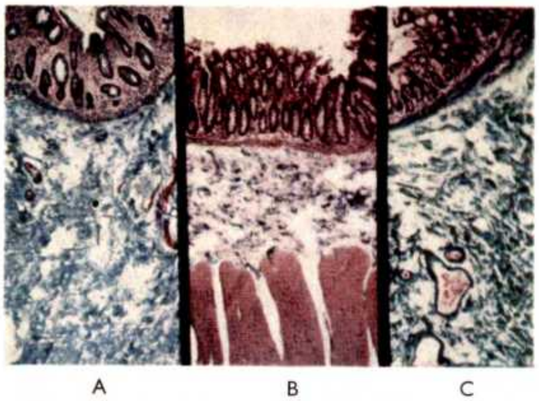

FIG. 1.—Photomicrograph showing greatly increased submucosal fibrous tissue in a section of colon damaged by radiation (A) contrasted with the normal appearance of colon (B) and the appearance of ischaemic colitis (C). (× 10.)

Table V.—TIME INTERVALS BETWEEN COMPLETION OF RADIOTHERAPY AND THE DEVELOPMENT OF SYMPTOMS OF SMALL-BOWEL COMPLICATIONS

COMPLICATION	NO. OF PATIENTS	TIME INTERVALS			
		<6 mth.	<1 yr.	1–5 yr.	>5 yr.
Steatorrhoea	6	3	2	0	1
Stricture	11	6	2	3	0
Spontaneous necrosis or fistula	8	1	2	3	2

Table VI.—MALABSORPTION FOLLOWING PELVIC RADIOTHERAPY

Malabsorption or Deficiency	*Manifestation*	*No. of Patients*
Fat	Steatorrhoea	6*
Vitamin B_{12}	Impaired Schilling test	5†
Calcium	Tetany (1 patient)	2‡

* Range, 11·8–39 g. per 24 hours.

† Range, 0·3–2·9 per cent per 24 hours.

‡ In one patient the level in the serum was 5·7 mg. per 100 ml. and that in the urine 34 mg. per 24 hours; in the other patient the level in the serum was 8·4 mg. per 100 ml and that in the urine 10 mg. per 24 hr.

Patients with large-bowel complications presented with rectal bleeding, alteration of bowel habit, and the passage of mucus per rectum. Colicky lower abdominal pain was associated with stricture formation, and pain on defaecation was associated with rectal ulcers and anal strictures. Perforation of the rectum caused a pelvic abscess in 2 patients and generalized peritonitis in a third. A rectovaginal fistula was the presenting complaint in another patient.

Symptoms of small-bowel complications included alteration in bowel habit and colicky abdominal pains. Three patients developed intestinal obstruction from small-bowel strictures, and 'spontaneous' necrosis of the bowel occurred in 6 patients, 2 of whom presented with generalized peritonitis and 2 with a pelvic abscess. The necrotic bowel was adherent to the uterus and side wall of the pelvis in the remaining 2 cases and perforation had not occurred.

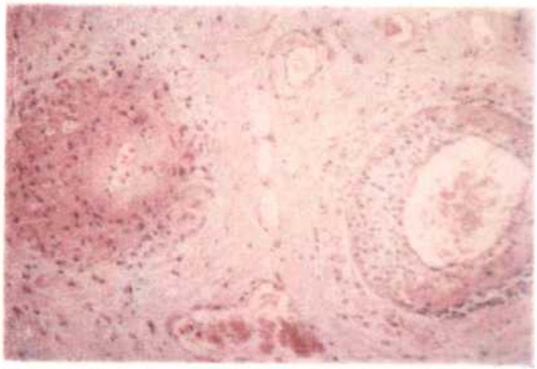

FIG. 2.—Photomicrograph showing the arterial sclerosis typical of radiation damage. (× 40.)

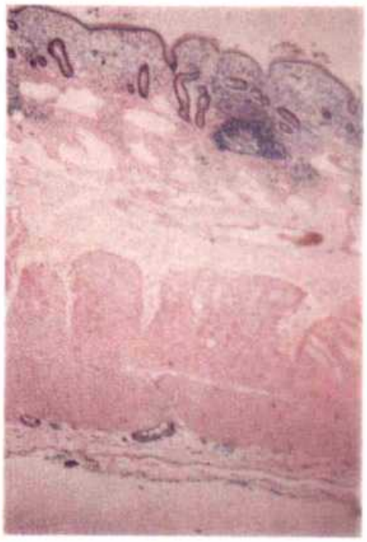

FIG. 3.—Photomicrograph showing submucosal lymphatic ectasia in the ileum of a patient with post-radiotherapy malabsorption. There is also loss of villi with simplification of the epithelium. (× 10.)

Small-bowel anastomoses failed to heal after surgical operations in 6 patients. In 5 of these patients there had been no symptoms to indicate that the intestine had been damaged by radiotherapy. One such postoperative patient developed an ileovaginal fistula and the others presented with peritonitis and faecal fistula. Further resection of bowel was undertaken in 4 cases, but the new anastomoses also became necrotic and the patients died.

Evidence of malabsorption of fat, vitamin B_{12}, and calcium was found (*Table VI*). The faecal fat (39 g. per 24 hours) exceeded the daily intake (30 g. per 24 hours) in 1 out of 6 patients with steatorrhoea, causing a 'fat-losing enteropathy'. The Schilling test indicated defective vitamin B_{12} absorption in 5 patients. One of the 2 patients with calcium deficiency presented with tetany 2 months after the resection of a small-bowel stricture.

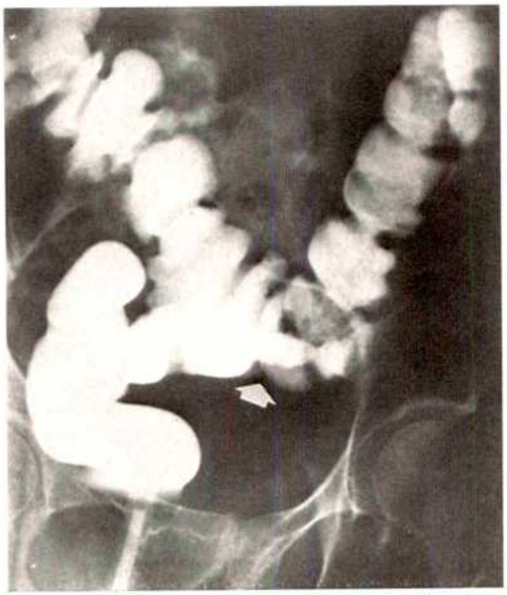

FIG. 4.—Barium-enema film showing the smooth and concentric outline of a post-irradiation stricture of the sigmoid colon (arrowed).

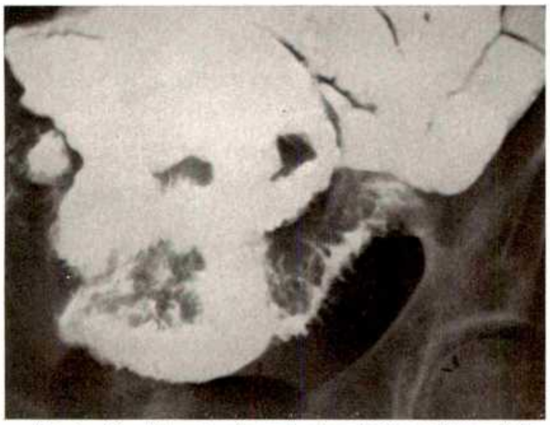

FIG. 6.—Small-bowel radiograph of a radiation stricture of the terminal ileum showing abnormal spiky appearance with narrowing and irregularity of the lumen.

The intestinal complications of radiotherapy caused the death of 14 patients (37 per cent), 9 of whom had no sign of recurrent tumour (*Table VII*). Spontaneous necrosis of the irradiated bowel or necrosis of an intestinal anastomosis accounts for 11 of the deaths. Only 3 patients (8 per cent) became completely asymptomatic after treatment of their bowel disease.

HISTOLOGY

The histological changes in the intestine after radiotherapy were first described by Warren and Friedman (1941). Such changes were found in all of the operative specimens obtained in the present series. Of particular interest was the increase in amount and density of the submucosal fibrous tissue (*Fig.* 1), well-developed arterial sclerosis (*Fig.* 2), and marked lymphatic ectasia which was present in 11 specimens (*Fig.* 3).

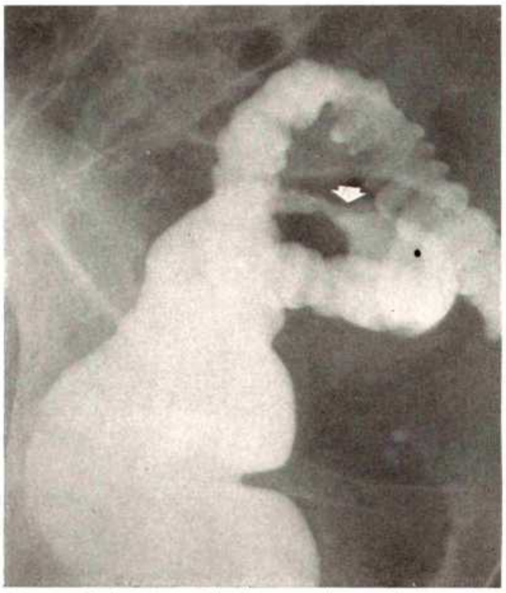

FIG. 5.—Barium-enema film demonstrating a radiation stricture of the colon (arrowed). There is irregularity and shouldering suggestive of malignancy.

Table VII.—CAUSE OF DEATH IN 14 PATIENTS WITH INTESTINAL COMPLICATIONS OF RADIOTHERAPY*

Complication	*No. of Patients*	*Cause of Death*
Necrosis of intestinal anastomosis or 'spontaneous' necrosis of intestine	11	Peritonitis 9 Postoperative intestinal obstruction 2
Rectovesical fistula	1	Uraemia
Stricture of ileum	1	Postoperative septicaemia
Proctocolitis and colorectal stricture	1	Postoperative bronchopneumonia

* Nine patients were free of tumour.

RADIOLOGY

Radiation strictures of the large bowel were generally smooth and concentric in outline (*Fig.* 4), but in 1 patient the stricture had the radiological features of malignancy (*Fig.* 5). A distinctive pattern was observed in the terminal ileum of 2 patients with small-bowel strictures (*Fig.* 6). The bowel lumen was narrowed with an irregular spiky outline, and folds of mucosa were drawn outside the contour of the bowel and angulated by adhesions. Nodular filling defects were also seen (*Fig.* 7). Striking mucosal changes were found in the small bowel. The normal feathery pattern was replaced by broad mucosal 'barring', and there was dilution of the barium in fluid-filled loops in 2 patients with steatorrhoea (*Fig.* 8). These changes are similar to those found in coeliac disease. Other patients were observed to have an extensive finer mucosal 'barring' throughout the majority of the small intestine (*Fig.* 9).

DISCUSSION

The latent period between the completion of radiotherapy and the development of symptoms of chronic intestinal damage varies from a few months to many years. More than one complication commonly occurs at the same time and further manifestations may develop later. Radiation damage should be regarded as a potentially progressive disease. The factors which may predispose to the development of intestinal complications have been suggested by several authors, including Bloedorn, Young, Cuccia, Mercado, and Wizenberg (1962), Graham and Villalba (1963), and DeCosse and others (1969). The dose of radiation is generally agreed to be an aetiological factor in some patients. In this series less than one-third of the patients had high doses of radiotherapy. Pelvic adhesions which may anchor a loop of bowel in the irradiated field have also been suggested as a factor. The equal incidence of pre-radiotherapy abdominal operations (or pelvic sepsis) in patients with small-bowel complications and in those sustaining damage to the already immobile rectum suggests that adhesions were not of aetiological importance in this series.

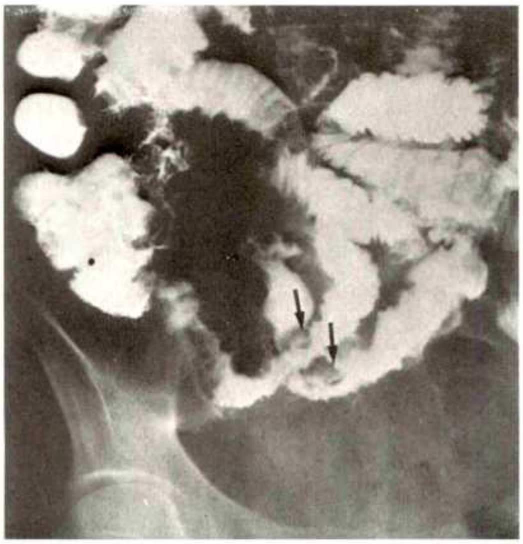

FIG. 7.—Small-bowel radiograph showing multiple nodular filling defects (arrowed) and narrowed lumen caused by radiotherapy.

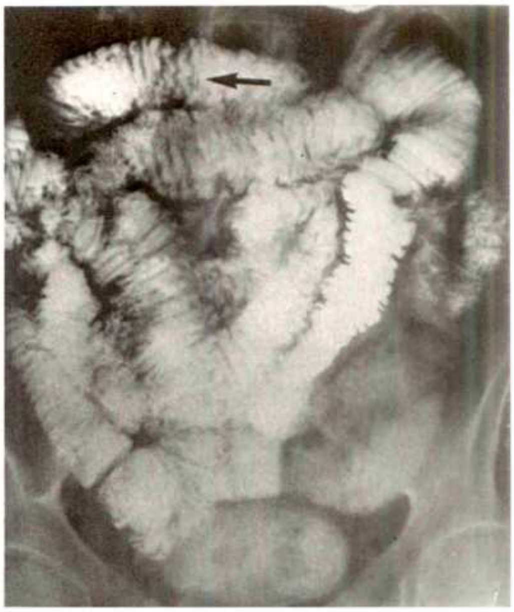

FIG. 8.—Small-bowel radiograph showing broad mucosal 'barring' (arrowed) and dilution of barium in fluid-filled loops.

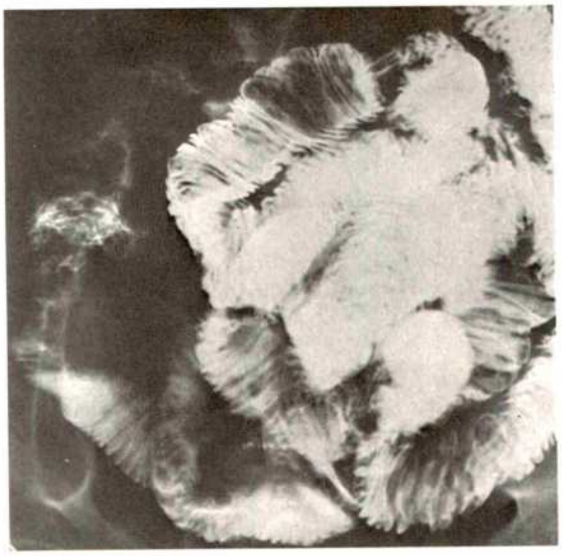

FIG. 9.—Small-bowel radiograph showing fine mucosal 'barring' in the small intestine. These changes were present throughout the majority of the small bowel.

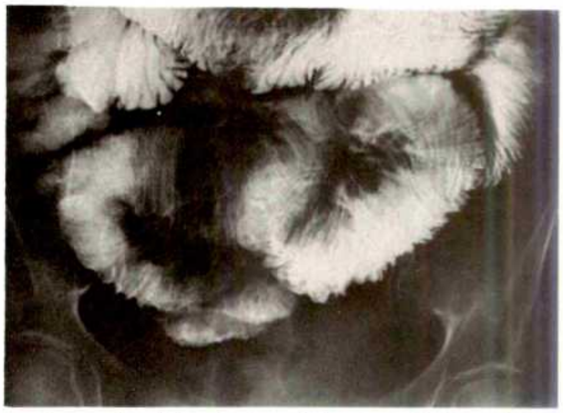

FIG. 10.—Small-bowel radiograph showing residual irregularity of outline and mucosal changes in a patient 2 months after the resection of an ileal stricture. At laparotomy the remaining intestine appeared macroscopically normal.

Calame and Wallach (1967) and DeCosse and others (1969) believed that the development of chronic intestinal complications is caused by vascular occlusion. Vascular sclerosis was prominent in the histology of specimens obtained in the present series and was associated with excessive deposition of dense fibrous tissue in the submucosa, producing an appearance similar to that seen in ischaemic colitis (*Fig.* 1). The late appearance of a rectovaginal fistula in 1 patient coinciding with the development of severe aorto-iliac atheroma also suggests that the precarious intestinal blood-supply caused by radiotherapy may become inadequate when in addition the general vascular state worsens.

Although there may be no clinical evidence of intestinal damage, sclerotic vessels in the intestinal wall may be unable to provide the increased blood-supply necessary for reparative processes, and post-radiotherapy intestinal anastomoses may fail to heal. All patients who have received pelvic or abdominal radiotherapy must be considered to be at risk if intestinal surgery is undertaken. The field irradiated in the treatment of pelvic cancer may extend as high as the lower border of the fourth lumbar vertebra, and long segments of bowel may therefore be inadvertently and unavoidably irradiated. The extent of the radiation damage may be much greater than is detectable macroscopically. This is illustrated by *Fig.* 10, which shows residual changes in the ileum after the apparently complete resection of a localized radiation stricture. Wide resection is therefore advisable and frozen-section examination of the bowel ends may be of value before anastomosis is performed (Higgins, Hamilton, and Hope-Stone, 1966). In the present series when primary healing of anastomosis did not occur further resection with restoration of intestinal continuity was uniformly unsuccessful and we feel that exteriorization of the bowel ends is a safer procedure in these circumstances. An unexpected finding was that severe malabsorption occurred in association with small-bowel lesions which were apparently localized. Possible aetiological factors include bile-salt malabsorption and the 'blind-loop' syndrome. Submucosal lymphatic ectasia was a prominent histological feature in this series and such lymphatic changes may be more extensive than is generally realized. It may be that the dilated submucosal intestinal lymphatics are secondary to radiation sclerosis obstructing the proximal lymph-vessels where they converge in the mesentery. This may explain the widespread alterations in mucosal pattern observed radiologically and the functional changes leading to malabsorption. The occurrence of a 'fat-losing enteropathy' following radiotherapy was reported by Tankel, Clark, and Lee (1965), and we confirm this in 1 patient in our series.

Radiological changes in the irradiated small bowel may mimic those seen in Crohn's disease, Whipple's disease, or coeliac disease and should not be confused with them. Multiple nodular filling defects resembling small-bowel metastases may also be seen (Mason, Dietrich, Friedland, and Hanks, 1970).

The diverse manifestations of the intestinal complications of radiotherapy may develop insidiously, are often progressive, and may be fatal. We advocate a combined surgical/radiotherapy clinic where close follow-up and investigation of patients at risk can be performed. Prompt radiological investigation of the large and small bowels should be performed if symptoms suggestive of radiation damage are elicited, and tests for malabsorption should be performed.

Acknowledgements.—We would like to thank Mr. H. E. Lockhart-Mummery and Dr. Thelma Bates for their helpful advice and the consultant staff of St. Thomas's Hospital, London, for permission to record the details of patients under their care.

Our head of table is unique.

The Matburn MS is a dramatic addition to our M table series, which are used in more countries throughout the world than any other operating tables.

The MS controls are grouped on a moveable selector arm at the head end to enable all major table movements to be made without disturbing the surgical team or the sterile area.

It's the most advanced table of its kind.

For further details and demonstration, please use the coupon.

THE AETIOLOGY OF HYPERTENSION AFTER RENAL TRANSPLANTATION IN MAN

By D. SAMPSON,
DEPARTMENT OF SURGERY, UNIVERSITY OF CAMBRIDGE

R. Y. KIRDANI, A. A. SANDBERG, AND G. P. MURPHY
ROSWELL PARK MEMORIAL INSTITUTE, BUFFALO, NEW YORK

SUMMARY

The renin-angiotensin-aldosterone system was studied in renal allograft patients, 70 per cent of whom were hypertensive.

Plasma-renin levels were found to be normal, and a normal increase was observed when patients were changed from the supine to the erect posture ($P < 0.01$). However, aldosterone-secretion rates were found to be approximately four times normal, and a positive correlation between these values and diastolic blood-pressure was observed ($r = 0.5$, $P = 0.05$). In patients with intact kidneys a highly significant correlation between plasma-renin activity and aldosterone-secretion rate was observed ($r = 0.8$, $P < 0.05$), but this normal correlation was not apparent in the patients with transplanted kidneys ($r = 0.1$, $P > 0.5$). Thus the aldosterone-secretion rates in these patients was not under the control of the renin-angiotensin system.

Concurrent studies in adrenalectomized patients showed that they also had elevated aldosterone-secretion rates, and the injection of ^{14}C-labelled cortisone acetate showed that they were capable of converting this steroid into aldosterone or an aldosterone-like metabolite. It is suggested that the hypertension seen after renal transplantation is related to the conversion of prednisone to a mineralocorticoid.

Further support for this hypothesis was obtained from studies in patients who had their therapy changed from daily prednisone to alternate-day methylprednisolone. They were found to secrete less aldosterone and all the patients became normotensive following this régime ($P < 0.01$). In addition, patients treated with an aldosterone antagonist, spironolactone, showed a prompt decrease in blood-pressure.

It is concluded that the denervated transplanted kidney is able to maintain normal blood-pressure homeostasis in man, and that hypertension seen after renal allografting is largely due to the therapy with immunosuppressive steroids.

RENAL transplantation has gained widespread acceptance in the treatment of terminal renal failure and to date nearly 10,000 of these operations have been carried out. One of the less desirable sequelae of these procedures has been the development of hypertension in a high proportion of allograft recipients (Starzl, Porter, Andres, and others, 1970). This increase in blood-pressure has been variously ascribed to the presence of the recipient's own diseased kidneys (Papadimitriou, Chisholm, and Shackman, 1969), stenosis at the arterial anastomosis of the transplant (Smellie, Vinik, and Hume, 1969), acute rejection (Pasternack, Kuhlback, Koivunen, Lindstrom, and Tiilikainen, 1970; Flanigan, Caldwell, Williams, Brewer, Glenn, Headstream, and Campbell, 1971), and chronic rejection (Starzl and others, 1970). While these factors undoubtedly play a role in the development of hypertension they do not account for the blood-pressure changes observed in the majority of patients.

We have previously shown that renal allograft recipients tend to have higher aldosterone-secretion rates than normal (Sampson, Kirdani, Sandberg, and Murphy, 1972), and that this occurs in spite of normal plasma-renin activity. In addition, we have shown that changes in the steroid therapy of these patients can profoundly influence the course of hypertension after a renal allografting procedure (Sampson and Albert, 1973). The preliminary studies suggested the possibility that orally ingested steroids can be converted in man to aldosterone or an aldosterone-like metabolite and that this hitherto undescribed phenomenon may account for the subsequent development of hypertension in renal transplant recipients.

The present report describes further studies on the renin-angiotensin-aldosterone system of both renal allografted and adrenalectomized patients which support the hypothesis that post-transplant hypertension is steroid dependent.

MATERIAL AND METHODS

Two groups of patients were studied, comprising 20 renal allograft recipients and 7 adrenalectomized subjects. Normal volunteers were used as controls, and some patients with renal disease were also included in the study. The patients with transplants were studied between 6 months and 2½ years after transplantation. These patients were studied while taking prednisone 10 mg. twice daily, and also after conversion to a régime of methylprednisolone, 32 mg. on alternate days. The patients also received azathioprine, 2 mg. per kg. per day, as additional immunosuppression. Serial blood-pressure determinations were carried out over a 6-month observation period. The patients were seen mainly in the out-patient clinic but were admitted to hospital for determination of 24-hour aldosterone-secretion rates and plasma-renin activity. Plasma-renin activity was estimated in both the supine and erect positions. For estimation during the supine position blood was collected at 8.00 a.m. after the patient had been in bed all night.

The patients then walked around the hospital for 4 hours and blood was again collected for determination of renin activity. The corresponding 24-hour aldosterone-secretion rates were determined after the patients had received 10 μc. 1,2-^{3}H-aldosterone intravenously. The 24-hour urine specimen following the injection was collected and assayed for tetrahydroaldosterone by a modification of the method of Nicolis, Wotiz, and Gabrilove (1968) using the gas chromatograph which we have described previously (Sampson and others, 1972).

Plasma-renin activity was determined by two methods. At the commencement of the study the rat bioassay was used (Gunnells, Grim, Robinson, and Wildenmann, 1967). During the course of the study a commercially manufactured radio-immunoassay kit became available (Schwatz-Mann Inc., New York) and this was subsequently used instead of the slower bioassay.

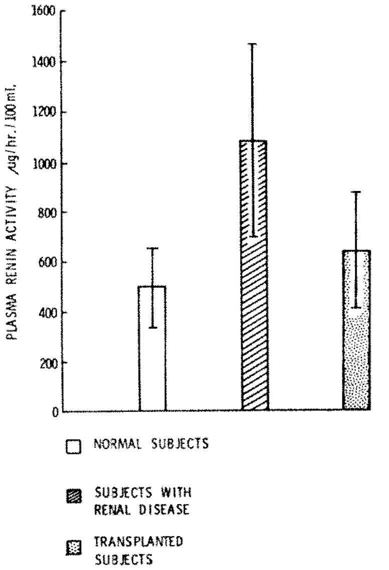

FIG. 1.—Plasma-resin activity in a group of renal allograft patients did not differ significantly from normal, while patients with renal disease had elevated levels. In this study a rat bioassay was used for the estimation of plasma-resin activity. (Values given as the mean ± S.E.M.)

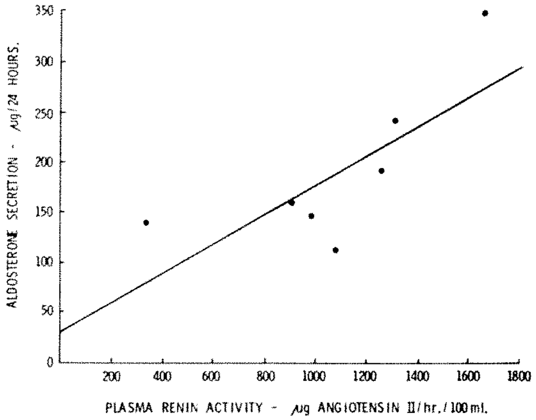

FIG. 3.—In a small sample of subjects with intact kidneys, some of whom had renal disease, a statistically significant positive correlation was observed between plasma-renin activity and aldosterone-secretion rate: $y = 0{\cdot}15x + 29$, $n = 7$, $r = 0{\cdot}8$, $P < 0{\cdot}05$. Patients with renal disease were included with normal subjects in order to obtain a wide range of values. The rat bioassay was used for the plasma-renin estimation.

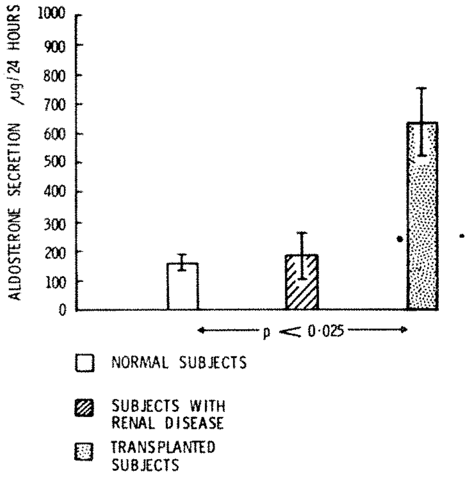

FIG. 2.—Aldosterone-secretion rates were significantly elevated in a group of renal allograft recipients. Patients with renal disease had normal aldosterone-secretion rates. (Values given as the mean ± S.E.M.)

The transplant patients were allowed a free diet with no sodium restriction, and diuretic and antihypertensive drugs were not given during the period of the renin or aldosterone assays. However, some hypertensive patients were treated with spironolactone, 25 mg. four times daily, once their baseline data had been established. All the transplant recipients had stable renal function and none had rejection episodes during the observation period.

The adrenalectomized patients were randomly selected from a population who had undergone this procedure for advanced prostatic carcinoma. These patients required maintenance therapy of cortisone acetate, 50 mg. by mouth daily. One of the patients studied in this group required additional medication with deoxycorticosterone acetate, 200 mg. per day, in order to prevent a life-threatening salt-losing state. The adrenalectomized subjects had their aldosterone-secretion rates determined in the same way as that for the transplant recipients, but in addition some of them were given 2 μc. ^{14}C-cortisone acetate intravenously, and the urine was then examined for tetrahydroaldosterone by comparing the peak activity obtained in the urine by chromatography with that produced by two known tetrahydroaldosterone standards. The urines of 6 of these patients were pooled for the specific identification of the aldosterone metabolite.

RESULTS

The plasma-renin activity for normal individuals, for patients with advanced renal disease, and for patients bearing renal allografts is illustrated in *Fig.* 1. Patients with renal disease had significantly higher renin activity than normal subjects ($P < 0{\cdot}05$), but the transplant recipients did not differ significantly from normal ($P > 0{\cdot}5$).

In contrast, *Fig.* 2 shows the aldosterone-secretion rates for the transplant patients to be significantly higher than normal ($P < 0{\cdot}05$) by a factor of about 4.

A comparison between plasma-renin activity and 24-hour aldosterone-secretion rates for normal individuals and those with diseased kidneys is shown in *Fig.* 3. The heterogeneous sample of patients was necessary in order to obtain a wide range of renin values with which to compare the corresponding aldosterone values. In the small number of patients examined a highly significant correlation between plasma-renin activity and aldosterone secretion was obtained ($r=0{\cdot}8$, $P<0{\cdot}05$).

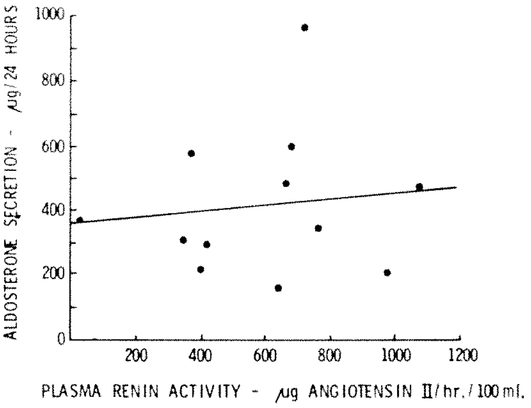

FIG. 4.—In a group of renal allograft patients maintained on an immunosuppressive steroid régime a slight but statistically insignificant positive correlation was observed between plasma-renin activity and aldosterone-secretion rate: $y=0{\cdot}1x+356, n=11, r=0{\cdot}1, P>0{\cdot}5$. This is in sharp contrast to the highly significant correlation shown in *Fig.* 3 for patients with intact kidneys.

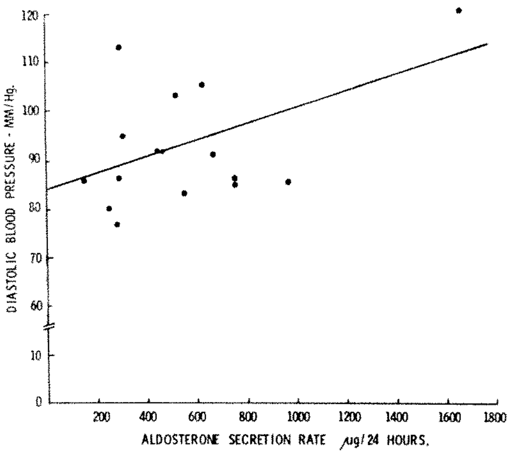

FIG. 6.—A significant correlation between diastolic blood-pressure and aldosterone-secretion rate was observed in a group of renal allograft patients: $y=0{\cdot}016x+84, n=15, r=0{\cdot}5, P<0{\cdot}05$.

A similar correlation carried out in the transplant patients, depicted in *Fig.* 4, shows there to be no significant relationship between the two variables ($r=0{\cdot}1$, $P>0{\cdot}5$). This reflects the fact that these patients secrete relatively large quantities of aldosterone in the presence of normal renin levels.

The response in terms of plasma-renin activity to changes of posture in the transplant patients is shown in *Fig.* 5. All the patients bearing a renal allograft were able to increase their plasma-renin levels following adoption of the erect posture. Using the paired *t*-test a highly significant difference between the supine and erect values was observed ($P<0{\cdot}01$). These results were obtained using the radio-immunoassay and, like the rat bioassay, indicate normal levels in the patients with transplants (normal value, $1{\cdot}25 \pm 0{\cdot}25$ ng. per hour per ml.).

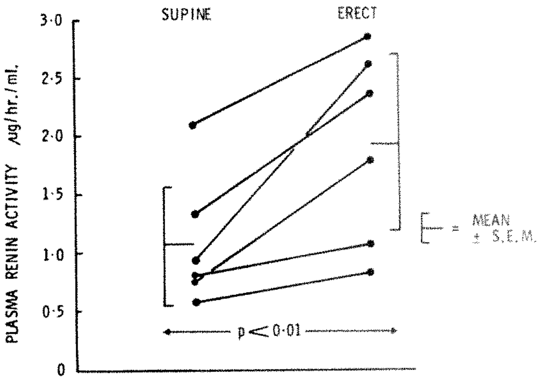

FIG. 5.—A highly significant rise in plasma-renin activity was observed when renal allograft patients adopted the erect position for 4 hours after having been supine for 8 hours. This is a normal response and the values are within the normal range. A radio-immunoassay was used for the plasma-resin estimations in this study.

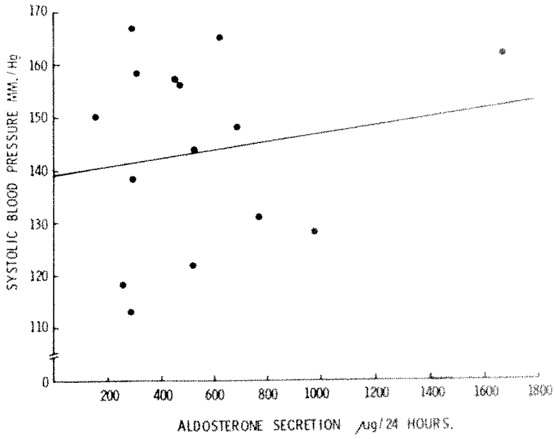

FIG. 7.—A slight positive correlation between systolic blood-pressure and aldosterone-secretion rate was seen in a group of renal allograft patients but this was not statistically significant: $y=0{\cdot}008x+139, n=15, r=0{\cdot}18, P>0{\cdot}5$.

The relationship between aldosterone-secretion rate and systolic and diastolic blood-pressure for patients bearing a renal allograft is shown in *Figs.* 6 and 7. While a slight positive correlation was seen for systolic blood-pressure and aldosterone-secretion rate this was not statistically significant ($r=0{\cdot}18$, $P>0{\cdot}5$). On the other hand, a more clearly defined positive correlation was seen for diastolic blood-pressure and aldosterone secretion which was statistically significant ($r = 0{\cdot}5$, $P = 0{\cdot}05$).

Figs. 8 and 9 illustrate the changes of systolic and diastolic blood-pressure which occurred when the transplant patients were switched from continuous therapy with prednisone to alternate day therapy with methylprednisolone. Each point shows the mean of serial observations taken over a 3-month period. Using the paired t-test a highly significant fall in systolic blood-pressure was seen following the change of therapy ($P < 0{\cdot}01$), and a fall in diastolic pressure was seen which was also statistically significant ($P < 0{\cdot}01$).

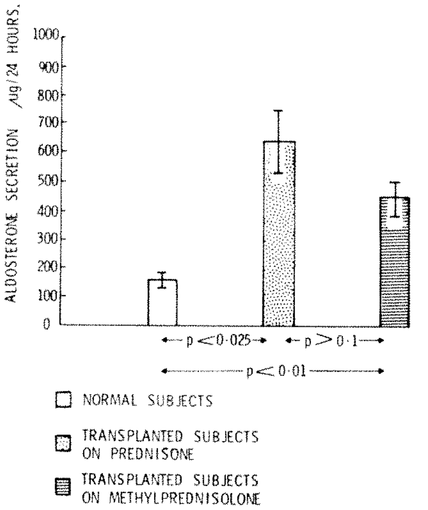

FIG. 8.—Effect of a change in steroid régime on aldosterone-secretion rate in transplant patients. The change from daily therapy with prednisone to alternate-day therapy with methylprednisolone resulted in a decreased aldosterone-secretion rate, but this was not statistically significant and the transplant patients continued to have significantly elevated secretion rates when compared with normal subjects. (Values given as the mean ± S.E.M.)

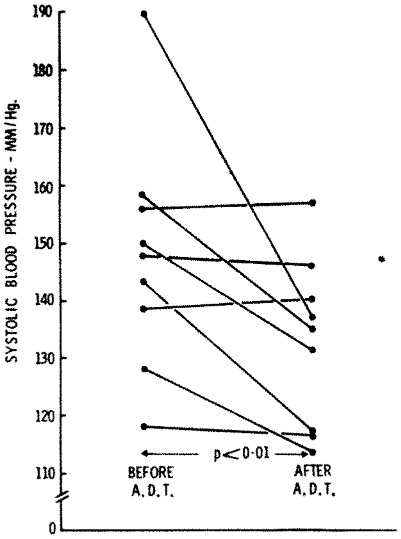

FIG. 9.—A highly significant fall in systolic blood-pressure occurred in transplant patients when the steroid maintenance therapy was changed from daily prednisone to alternate-day methylprednisolone. Each point represents the mean of serial observations taken over a 3-month observation period. P was derived from a paired t-test.

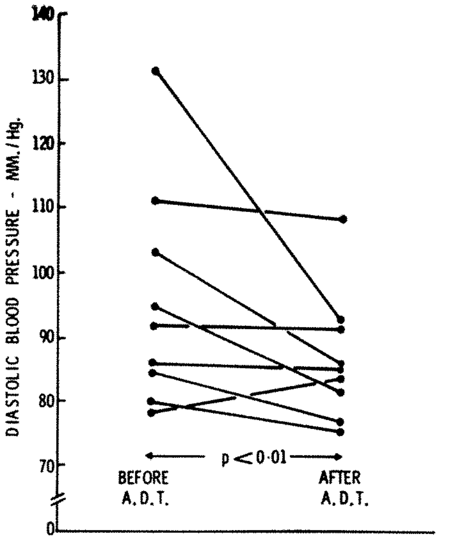

FIG. 10.—As for systolic blood-pressure, a highly significant drop in diastolic blood-pressure occurred when the steroid therapy in transplant patients was changed. The data were derived in the same way as for *Fig.* 9.

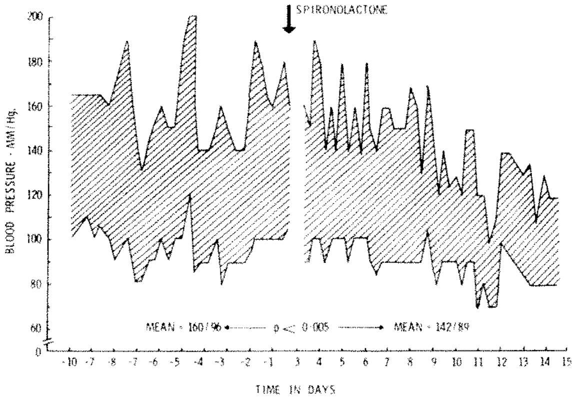

FIG. 11.—Serial blood-pressure determinations in a renal allograft patient before and after treatment with an aldosterone antagonist, spironolactone. A highly significant fall in both diastolic and systolic blood-pressure occurred following the treatment.

The effect of the change in steroid therapy on aldosterone-secretion rates in the transplant patients is shown in *Fig.* 10. While a drop in aldosterone secretion was seen after the change of therapy this was not statistically significant, and secretion remained significantly higher than normal.

An aldosterone-secretion rate determination carried out on an adrenalectomized patient as a check of the blank value surprisingly gave an excretion of 850 µg. per day (normal value, 160 ± 26 µg. per day). The urine of 6 further adrenalectomized patients, previously injected with 2 µc. of ^{14}C-cortisone acetate, showed a peak activity on paper chromatography which corresponded to a tetrahydroaldosterone standard. Further proof of aldosterone production by adrenalectomized patients was obtained by finding a peak corresponding to a tetrahydroaldosterone-γ-lactone standard, and following acetylation of both the standard and the patients' urine the two peaks continued to run together in a counter-current distribution system. Statistical analysis of the peaks of the standard and of the patients' urine showed them to be identical.

The adrenalectomized patient who required deoxycorticosterone acetate to prevent salt depletion was found to have no aldosterone secretion at all.

The renal transplant patients who were hypertensive postoperatively and were treated with spironolactone while on continuous prednisone therapy showed a fall in blood-pressure as a result of the use of the aldosterone antagonist. The blood-pressure record of such a patient is illustrated in *Fig.* 11. However, in a severely hypertensive 8-year-old transplant recipient no decrease in blood-pressure occurred following treatment with spironolactone. He was subsequently shown to have a stenosis of his transplant renal artery, and following surgical correction his blood-pressure returned to normal.

DISCUSSION

The finding of normal renin levels after renal transplantation is in agreement with the observations of others (Blaufox, Birbari, Hickler, and Merrill, 1966; Nielsen, Clausen, and Jensen, 1970). We found this to be the case both by the rat bioassay and the radio-immunoassay. Similarly, the normal increase in plasma-renin activity following the change of posture from the supine to the erect position which was observed after renal transplantation confirms the work of Greene, Vander, and Kowalczyk (1968), who also found that transplant recipients could increase their renin levels in response to sodium depletion. Thus, although it has been shown that an intact nerve-supply is necessary for normal renin responses in the dog (Mogil, Itsovitz, Russell, and Murphy, 1970), it seems that the completely denervated renal allograft in man maintains its normal renin responses. On this evidence, therefore, the renin-angiotensin system cannot be implicated in the development of hypertension after renal transplantation.

In contrast, aldosterone-secretion rates were greatly elevated in renal transplant recipients, and this was related to some extent to the degree of hypertension. Evidence has been obtained which suggests that a renal hormone exists which stimulates the adrenal gland to secrete aldosterone (Davis, Carpenter, Ayers, Holman, and Bahn, 1961; Ganong and Mulrow, 1961), and it has been subsequently demonstrated that this is almost certainly angiotensin II (Peart, 1970). Laragh, Sealey, and Sommers (1966) have shown a close correlation between plasma-renin activity and aldosterone-secretion rate in both normal and hypertensive subjects, and our studies in volunteers and patients with renal disease have shown the expected correlation. However, such a correlation could not be observed in the transplant patients, the implication again being that in these individuals the aldosterone-secretion rate had escaped from the normal renal control mechanisms.

Surprisingly a chromatographic peak corresponding to tetrahydroaldosterone was observed in adrenalectomized patients, and subsequent injection of labelled cortisone acetate resulted in the label being detected in the peak corresponding to tetrahydroaldosterone. To date there is no known pathway for the conversion of cortisone to aldosterone, and it could be that an aldosterone-like metabolite is being detected. However, the data strongly suggest that such a conversion is possible. The secretion rates that we have observed agree well with the normal values of others, and the close correlation with the plasma-renin activity in subjects with intact kidneys suggests that the assay is reliable.

The role of maintenance steroids in controlling the apparent aldosterone-secretion rate was further suggested by the finding of a decrease when continuous prednisone therapy was changed to alternate-day therapy with methylprednisolone. Although the subsequent decrease in aldosterone-secretion rate was not significant statistically, this may have been due to the small number of patients studied. Concurrent with the observed fall in aldosterone-secretion rate, a highly significant fall in both systolic and diastolic blood-pressure occurred following the change of steroid therapy. It was of interest in this respect that the patient who required deoxycorticosterone acetate supplements in addition to cortisone acetate following adrenalectomy had no detectable aldosterone in the urine. It is possible that such patients are unable to convert orally administered cortisone to a mineralocorticoid.

Of course, further proof of the role of steroid in the genesis of hypertension after transplantation could be obtained by withholding such drugs, but such a study is not possible at present. However, a transplant recipient who received no steroids has been reported (Rosenfeld, Levi, de Vries, and Levy, 1971), and this patient remained completely normotensive for a 5-year postoperative observation period.

One of the features of hypertension secondary to mineralocorticoid excess is a prompt response to the use of aldosterone antagonists such as spironolactone, (Spark and Melby, 1971). The hypertensive transplant recipient depicted in *Fig.* 11 showed just such a good response to treatment with spironolactone, which was further evidence that the hypertension in her case was related to excessive mineralocorticoid production. No such response was seen in the patient whose hypertension was the result of stenosis of the renal transplant artery.

It is common to treat renal allograft patients with high doses of steroids in the early postoperative period, and hypertension has been observed to be a very frequent postoperative complication, especially in children (Gonzalez, Martin, West, Spitzer, and McEnery, 1970; Fine, Edelbrock, Brennan, Grushkin, Korsch, Riddell, Stiles, and Lieberman, 1971; Najarian, Simmons, Tallent, Kjellstrand, Buselmeier, Vernier, and Michael, 1971). Thus, steroid therapy is strongly implicated in the aetiology of the hypertension, as all these authors agree that this complication becomes less of a problem as the steroid dosage is reduced.

In conclusion, it is suggested that the main cause of hypertension after renal transplantation in man is use of steroids for immunosuppressive therapy. This contention is based on the following observations:—

1. In the renal allograft patient bearing a denervated kidney the renin system is normal.

2. Aldosterone-secretion rates are elevated in renal transplant recipients.
3. In transplant patients there is a positive correlation between blood-pressure and aldosterone-secretion rate.
4. Adrenalectomized patients receiving maintenance steroid therapy have been shown to have aldosterone or an aldosterone-like substance in the urine, and labelling studies suggest that this is derived from administered cortisone.
5. A change of steroid therapy in transplant patients which tends to reduce the apparent aldosterone-secretion rate is accompanied by a significant fall in blood-pressure.
6. Treatment of hypertensive transplant patients with an aldosterone antagonist, spironolactone, can result in a significant fall in blood-pressure.

THE ROLE OF CELLULAR IMMUNITY IN CONTROL OF NEOPLASIA

By G. BONE and R. CAMPLEJOHN

DEPARTMENT OF SURGERY AND PATHOLOGY, UNIVERSITY OF NEWCASTLE UPON TYNE

SUMMARY

Using assessment of the delayed hypersensitivity response to a new antigen—in this study 2-4-dinitrochlorobenzene—as a measure of cellular immunity in patients with rectal cancer has shown highly significant correlation with pathological staging. No relationship between cellular immunity and rate of proliferation of rectal tumours could be established. The significance of these results is discussed.

Despite a more aggressive technical approach the results of surgery for carcinoma of the rectum have not improved over the past 30 years (Registrar General, 1969). Further increase in survival rates will depend on the exploitation of any factors which will assist in the eradication of malignant cells; therefore a fundamental question in cancer research is to determine the extent to which patients possess the ability to delay or to control the progress of malignant disease.

Immune mechanisms have often been implicated as possible factors in the restriction of neoplastic proliferation (Himmelweit and Ehrlich, 1957), and there is an impressive accumulation of evidence to support the concept of immunological surveillance in neoplasia (Burnet, 1970). For example, it has been found that in patients with reduced immunological competence, either congenital or iatrogenic, there is an increased incidence of neoplasia (Dent, Peterson, and Good, 1968; Penn, 1970), and assessment of cellular immunity in patients with malignant disease using their cutaneous delayed hypersensitivity responses to various antigens has shown a decreased ability to respond as the disease progresses (Hughes and Mackay, 1965; Solowey and Rapaport, 1965). Furthermore, inability to produce delayed hypersensitivity to new antigens after initial sensitization has been found to correlate with early recurrence of malignant growth after surgery (Eilber and Morton, 1970). Other evidence supporting immunological control of malignant proliferation is that cancer is more likely to be initiated at the extremes of life

(Registrar General, 1969) when the effectiveness of the immune system is low as assessed by *in vivo* and *in vitro* tests (Sample, Gertner, and Chretien, 1971). Further confirmation is that there is a significant correlation between the relative intensity of lymphocyte infiltration in a tumour and length of survival of the patient (Black, Opler, and Speer, 1954; Lauder and Aherne, 1972).

Thus, there is powerful support for cellular immune control of neoplastic spread but little is known about the actual mechanisms involved. We know that a cancer may increase in mass either by an increased rate of proliferation or by a decreased rate of cell loss as compared with the tissue from which it arises, so that either restriction of proliferation or encouragement of cell loss could play a role.

A study was planned to investigate cellular immunity in patients suffering from rectal carcinoma by assessing their cutaneous delayed hypersensitivity responses to 2-4-dinitrochlorobenzene (DNCB) after initial sensitization with this chemical. In addition, the rate of proliferation of the rectal carcinomas and the mucosa from which they arise was measured using a stathmokinetic technique (Refsum and Berdal, 1968). In this way any evidence of restriction of proliferation of malignant cells by cellular immune mechanisms could be discovered.

MATERIAL AND METHODS

Patients.—Forty patients (age range, 36–81 years, mean age, 62 years), 23 males and 17 females, suffering from adenocarcinoma of the rectum were selected from the general surgical wards of one hospital. All the patients had biopsies confirming their malignant disease and all were submitted to operation. Patients who had received radiotherapy, chemotherapeutic drugs, or corticosteroids were excluded from the study. From this group of patients 21 had an estimation of the proliferative rates of their tumours performed. The rate of proliferation of the normal mucosa from which the tumour arose was studied in 11 cases.

Control Patients.—Twenty patients from the same hospital population were used as controls (age range, 44–80 years, mean age, 64 years); there were 9 males and 11 females. All were admitted for large-bowel investigations; 7 patients had no obvious pathology and 13 were found to have diverticulosis.

Clinical and Pathological Staging.—The clinical assessment of the extent of the disease was noted for each patient at laparotomy; particular care was taken to record any evidence of liver metastases.

A pathological grading was obtained for patients whose neoplasms were resected.

The classification of Dukes was used and a further category, D, was added to denote signs of widespread metastases.

Classification.—

A, Rectal cancer limited to the wall of the rectum.
B, Extrarectal spread but no lymphatic metastases.
C, Lymphatic metastases.
D, Distant metastases.

DNCB Sensitization and Testing.—The technique employed was adapted from that of Ratner, Waldorf, and Scott, 1968). The patients were sensitized by the application of 4000 μg. of DNCB dissolved in acetone and applied to a 3-cm.^{2} area of skin on the volar aspect of a forearm. An occlusive polythene dressing was put over the site and left in position for 4 days.

Sensitivity tests were carried out by applying four A1 patch test squares (Imeco, A.B., Stockholm), each impregnated with a different strength of DNCB in acetone (200, 100, 40, and 2 μg.). These squares were applied to the opposite forearm *at least* 14 days after sensitization. The test was read at 48 hours. A positive response showed erythema and induration under the patch test square.

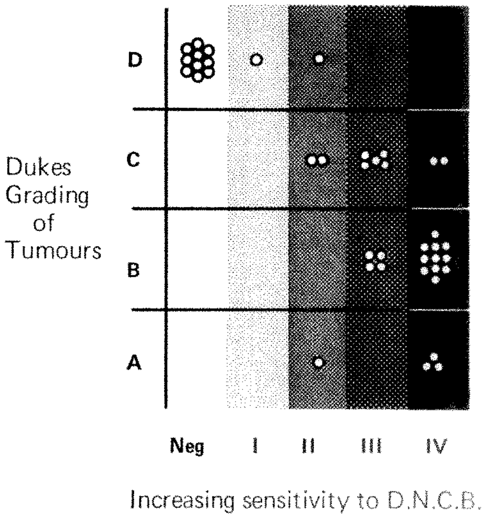

FIG. 1.—Relationship of tumour grading to DNCB sensitivity.

Table I.—CUTANEOUS DELAYED HYPERSENSITIVITY RESPONSES TO DNCB IN CANCER AND CONTROL PATIENTS

PATIENTS	RESPONSE TO DNCB					TOTAL
	Negative	Grade I	Grade II	Grade III	Grade IV	
Cancer	10	1	4	9	16	40
Control	1	0	4	11	4	20

Patients were then graded according to their sensitivity: negative; grade I (sensitive to 200 μg. only); grade II (sensitive to 100 μg.); grade III (sensitive to 40 μg.), and grade IV (sensitive to 2 μg.).

Findings.—*Table I* shows the gradings of the cancer and control groups. Twenty-five per cent of the cancer patients had a negative response, i.e., evidence of poor cellular immunity, compared with only 5 per cent of the control patients. Nevertheless 40 per cent of the cancer patients had a grade IV reaction, i.e., evidence of good cellular immunity.

Fig. 1 shows the relationship of the patients' cellular immunity as assessed by their response to DNCB to the pathological grading of their tumours. There is an obvious relationship between good cellular immunity and favourable grading. This also corresponds with prognosis, for within 6 months of operation all the anergic patients were dead whereas only 2 of the patients with good responses were dead, both dying from cardiac conditions.

Table II shows a comparison of the patients without metastases (tumour grades A and B) and those with metastases (tumour grades C and D) with their respective responses to DNCB. Sensitivity grades I and II have been grouped together for statistical analysis.

The results show that there is a homogeneity between the groups ($\chi^2 = 20{\cdot}86$, d.f. $= 3$, $P < 0{\cdot}001$) and that there is a linear trend ($\chi^2 = 20{\cdot}29$, d.f. $= 1$, $P < 0{\cdot}001$) with no significant deviation from this trend ($\chi^2 = 0{\cdot}57$, d.f. $= 2$, $P > 0{\cdot}3$). In other words there is a highly significant relationship between cellular immune competence and the degree of progression of the malignant disease.

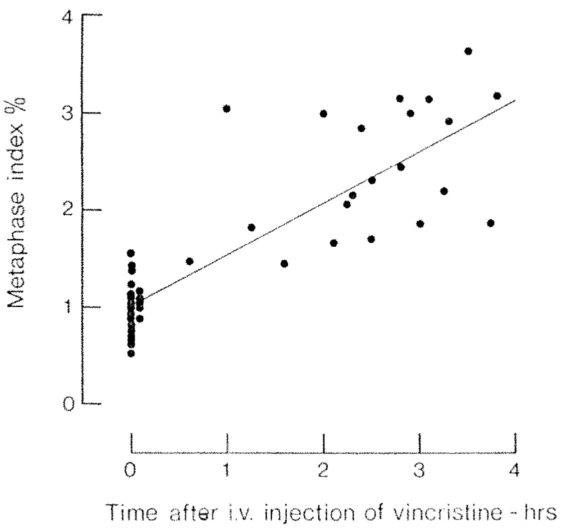

FIG. 2.—Metaphase index compared with time after the injection of vincristine. The regression line was obtained by the least-squares regression method.

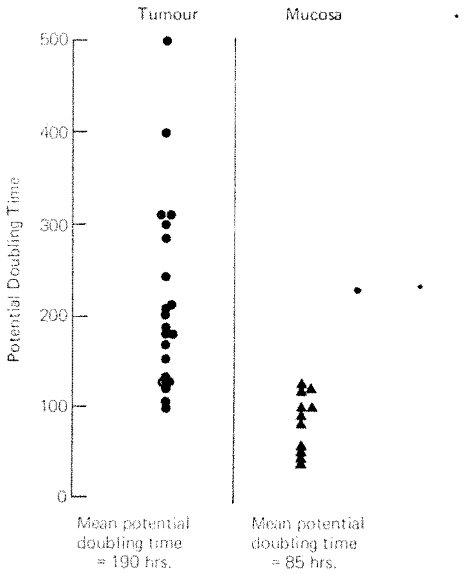

FIG. 3.—Proliferation rates of rectal tumour and mucosa.

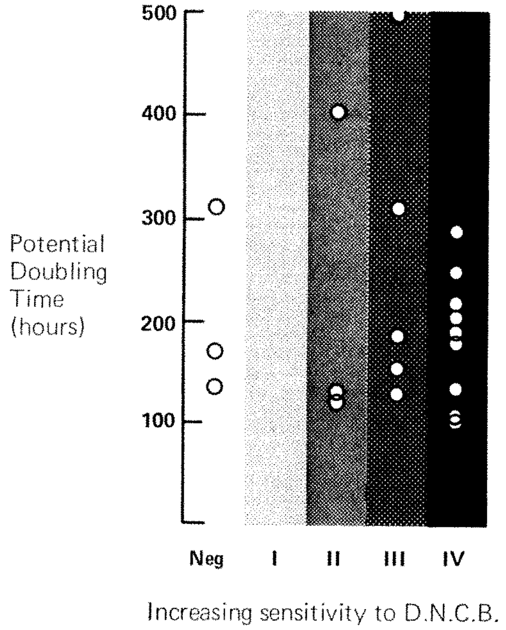

FIG. 4.—Relationship of tumour proliferation to DNCB sensitivity.

Table II.—CORRELATION OF TUMOUR GRADING WITH SENSITIVITY TO DNCB

GRADING OF TUMOURS	SENSITIVITY TO DNCB				TOTAL

Estimation of Cell Birth-rate.—This was estimated by using a stathmokinetic agent (vincristine sulphate) which blocks proliferating cells in mitosis.

First, a biopsy was taken from the tissue (either tumour or mucosa) to be studied. Further biopsies were taken at known time intervals after the intravenous injection of a single dose of vincristine sulphate (Lilly), 0·045 mg. per kg. Histological slides were prepared in the usual manner from the biopsy specimens and stained with haematoxylin and eosin. Using an eyepiece graticule 6000 tumour cells were counted and the number of metaphases and other stages of mitosis were noted. For the mucosal specimens whole crypt counting was employed and the total number of cells (usually 6000–8000) and mitoses in 100 crypts per biopsy were counted. The metaphase index, which is the number of metaphases per 100 cells, was calculated for each specimen. The increase in the index following vincristine was plotted against time and the rate of entry into mitosis per hour was obtained.

Although all stages of mitosis (i.e., prophase, metaphase, anaphase, or telophase) were scored when present, metaphase counts rather than mitotic counts were used for the purpose of calculation. Metaphase counts were considered to be more reliable because prophases in particular proved difficult to recognize and may have been underestimated. This is not the case with metaphases, which were easily recognized.

Fig. 2 shows the results of metaphase counts made on the tumour biopsy specimens. The results from the 21 tumour cases were pooled and the metaphase index was plotted against time after the injection of vincristine. The line best fitting the points was obtained by the least-squares regression method. This line gives the mean rate of entry into mitosis for these tumours, and the reciprocal of the slope of the line gives a parameter called either the potential doubling time TP(D) or the apparent cell cycle time TC(a). The value obtained was 190 hours. This is the time that the tumour would take to double in size if no other factors were acting. Using the same technique for the rectal mucosal specimens the mean potential doubling time was found to be 85 hours. *Fig.* 3 shows the proliferation rates of individual cases of both tumour and mucosa. These results show that the mean proliferation rate of the rectal mucosa is more than twice that of the rectal carcinomas.

Fig. 4 shows the potential doubling times of each rectal carcinoma studied plotted against the response to DNCB in the patient in whom it arose. There is no significant correlation, indicating that cellular immunity as assessed by DNCB sensitivity tests has no obvious effect on the proliferation rates of the rectal tumours.

DISCUSSION

This study was initiated to investigate the proliferation rate of rectal carcinomas and to establish whether cellular immune mechanisms have the ability to repress proliferation. We have shown that in rectal carcinomas the rate of proliferation does not exceed that of the rectal mucosa from which they arise. The increase in volume of these tumours must therefore be due to a reduced cell loss as compared with rectal mucosa, the rate of cell loss in the mucosa being 100 per cent, i.e., for every cell produced one is lost.

Steel (1968) has shown that cell loss (ϕ) can be calculated from the formula:—

$$\phi = 1 - \frac{\text{Potential doubling time}}{\text{Actual doubling time}}\,.$$

We have calculated that the potential doubling time for rectal carcinomas is 190 hours. Welin, Youker, Spratt, Linnell, Spjut, Johnson, and Ackerman (1963) have measured the actual doubling time in a group of 20 rectal carcinomas using a double-contrast barium-enema technique and found the mean doubling time to be 620 days. If we substitute these figures in the formula we obtain

$$\phi = 1 - \frac{190 \text{ hours}}{14{,}880 \text{ hours (620 days)}}$$
$$= 0{\cdot}987 \text{ (or } 98{\cdot}7 \text{ per cent).}$$

In other words, for every 100 cells produced in rectal carcinomas 99 are lost. This difference between the cell loss of 100 per cent in the mucosa and 98·7 per cent in tumours is enough to account for the growth of tumours. These findings are in accord with those of Spratt and Ackerman (1961), who calculated a net increase of only 1 cell per 1000 cells per day in a patient whose rectal carcinoma was studied with serial barium enemas over a period of 7·5 years.

We have also shown that there is no correlation between the rate of proliferation of the rectal carcinomas and the cellular immune competence of the individual patients as assessed by their cutaneous delayed hypersensitivity response to DNCB. However, there is a good correlation between a strong response to DNCB and a favourable pathological and operative staging of the growths. This would indicate that although cellular immunity as assessed by delayed hypersensitivity reactions is concerned with control of neoplastic spread the effect is not mediated by a restriction of the proliferation rate of the tumours.

It is more probable that cellular immunity acts by altering the percentage of cells lost either in the tumour or its metastases. Thus in cases with good immune competence cell loss should approach 100 per cent and the reverse would occur with decreased competence. These findings have important implications as to the management of rectal carcinomas, especially when planning adjuvant therapy together with surgery.

INHIBITION OF HUMAN GASTRIC SECRETION BY PROSTAGLANDIN

BY D. C. CARTER, S. M. M. KARIM, D. BHANA, AND P. A. GANESAN

UNIVERSITIES OF EDINBURGH AND MAKERERE, UGANDA

SUMMARY

The synthetic analogue prostaglandin 15(R)15 methyl-E_2 methyl ester is a potent inhibitor of basal and pentagastrin-induced acid secretion when given orally to male volunteers. Intravenous injection of the same dose of the analogue did not result in significant inhibition. The analogue is thought to reduce acid secretion by a direct effect on the parietal cell and differs from its parent prostaglandin E_2 by its resistance to rapid enzymic degradation.

The possible physiological significance of prostaglandin E_2 in human gastric secretion is considered and the potential therapeutic role of its 15(R)15 methyl analogue is discussed.

PROSTAGLANDIN E_2 (*Fig.* 1) is now known to occur naturally in human gastric mucosa (Bennett, Murray, and Wyllie, 1968), but a physiological role for this compound has not yet been defined. In a recent preliminary communication we reported that prostaglandin E_2 did not inhibit basal acid secretion in man when given orally but that marked inhibition followed oral administration of its synthetic analogue 15(R)15 methyl-E_2 methyl ester (*Fig.* 1) (Karim, Carter, Bhana, and Ganesan, 1973). The study of this analogue has now been extended to an assessment of its effect on basal secretion when given orally or intravenously and on pentagastrin-induced secretion when administered orally. The results of this extended study will be discussed in terms of the therapeutic potential of the compound and the possible physiological significance of prostaglandin E_2 in human gastric secretion.

MATERIALS AND METHODS

All tests were performed on healthy male volunteers without previous dyspeptic history.

In 11 tests 200 μg. of prostaglandin 15(R)15 methyl-E_2 methyl ester were given orally to assess its effect on basal acid secretion, while in 9 tests the same dose was administered by bolus intravenous injection. For 17 of these tests data are available from control studies of basal secretion in the same individuals.

In 12 subjects 200 μg. of the analogue were given orally to challenge the acid secretion induced by pentagastrin (6 μg. per kg. i.m.). In all 12 cases control tests were performed using pentagastrin alone. Four of the 12 subjects underwent an additional two tests in which 50 and 100 μg. of prostaglandin were given orally to challenge pentagastrin-induced secretion.

After a 12-hour overnight fast a nasogastric tube (FG 14–16) was passed into the stomach and the fasting residue was discarded. The tube position was adjusted to allow the ready recovery of a trial 20-ml. instillate of water and continuous suction (2–4 mm. Hg) was then applied. Tube patency was ensured by periodic air insufflation. Specimens of gastric juice were collected every 15 minutes and assessed in terms of volume (ml.), *p*H, acid concentration (mEq./l.), and acid output (mEq.). Titrations were performed to end-point *p*H 7 using a glass electrode and 0·05 *N* NaOH solution.

After a basal period of two 15-minute collections the prostaglandin analogue was administered. For oral administration the dose was diluted to 10 ml. with water and instilled through the nasogastric tube. Suction was discontinued for 30 minutes to allow contact with the gastric mucosa. Collection was then restarted and continued for a further 3 hours. Where oral administration was used to challenge pentagastrin-induced secretion the pentagastrin (6 μg. per kg. i.m.) was injected at the moment of recommencing aspiration. When prostaglandin was given intravenously the dose was diluted to 2 ml. with *N* saline and given at the end of the basal period. Collection of gastric juice was then continued for 3 hours.

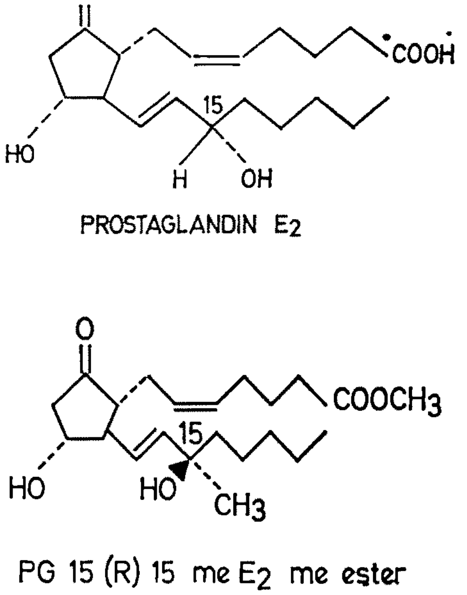

FIG. 1.—Chemical structure of prostaglandin E_2 and 15(R)15 methyl-E_2 methyl ester.

Control tests differed only in the exclusion of prostaglandin from the vehicle of administration. The order of the control test and the test using prostaglandin was randomized.

Subjects were questioned specifically during the tests for untoward gastro-intestinal and other side-effects and asked to report any alteration in bowel habit in the succeeding 24 hours.

RESULTS

No adverse side-effects or alteration in gastro-intestinal function were reported in any tests using the prostaglandin analogue.

Effect of Prostaglandin 15(R)15 Methyl-E_2 Methyl Ester on Basal Acid Secretion.—

Oral Administration (11 tests).—As shown in *Fig.* 2 a marked and sustained reduction in acid secretion was noted in all the cases after the oral administration of 200 μg. of the analogue. In 8 cases the aspirate became alkaline after instillation of the dose. Control tests were performed in 9 individuals and, as shown in *Table I*, the mean 3-hour acid output in control studies was reduced by 76 per cent by prostaglandin administration, a reduction which is statistically highly significant ($t = 5{\cdot}80$, $P < 0{\cdot}001$).

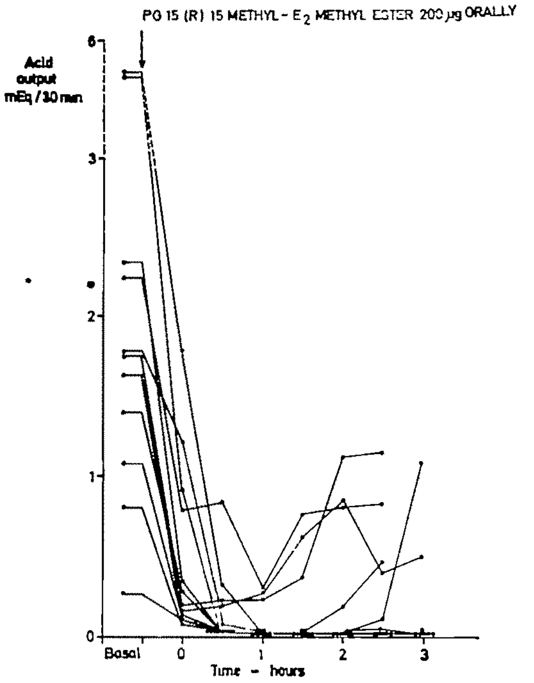

FIG. 2.—Effect of oral administration of 200 μg of prostaglandin 15(R)15 methyl-E_2 methyl ester on basal acid output.

Table I.—EFFECT OF PROSTAGLANDIN 15(R)15 METHYL-E_2 METHYL ESTER ON BASAL ACID SECRETION

ROUTE OF ADMINISTRATION	NO OF TESTS	MEAN 3-HOUR ACID OUTPUT AFTER PROSTAGLANDIN (mEq.)	MEAN CONTROL 3-HOUR ACID OUTPUT (mEq.)	MEAN PERCENTAGE REDUCTION IN 3-HOUR ACID OUTPUT
I.v. bolus	8	7·50 ± 1·08	9 69 ± 1·49	24·5
Oral	9	1·94 ± 0·58	8·09 ± 1·01	76

In all the cases the fall in acid output after prostaglandin administration resulted primarily from a reduction in acid concentration rather than an effect on the volume of secretion (*Fig.* 3).

Intravenous Administration (9 tests).—In only 1 subject was a marked and sustained rise in the *p*H of the aspirate observed following prostaglandin injection. In one other subject the *p*H rose transiently to 5·3 after prostaglandin injection, but in the remaining 7 tests no definite inhibition of acid secretion was noted (*Fig.* 4). This is reflected in a comparison with the 3-hour acid output in the corresponding control tests. As shown in *Table I* the mean 3-hour output in control studies was only reduced by 24·5 per cent following prostaglandin injection, a reduction which is not statistically significant ($t = 1{\cdot}51$, $p > 0{\cdot}10$).

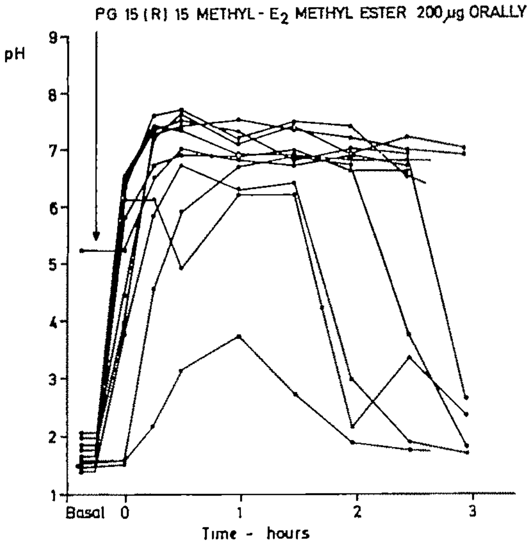

FIG. 3.—Effect of oral administration of 200 μg of prostaglandin 15(R)15 methyl-E_2 methyl ester on the *p*H of the gastric aspirate

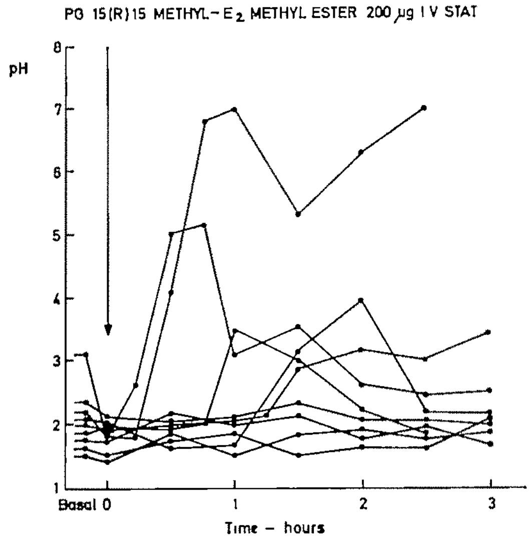

FIG. 4.—Effect of bolus intravenous administration of 200 μg. of prostaglandin 15(R)15 methyl-E_2 methyl ester on the *p*H of the gastric aspirate.

Effect of Prostaglandin 15(R)15 Methyl-E_2 Methyl Ester on Pentagastrin-induced Secretion.—

In all but one of the 12 individuals tested the maximal acid output (M.A.O. = sum of the four highest consecutive 15-minute samples after pentagastrin injection, expressed as mEq. per hour) was lowered by prior instillation of the prostaglandin analogue. A comparison between the M.A.O. after pentagastrin alone and the M.A.O. when pentagastrin was preceded by prostaglandin is shown in *Fig*. 5. A mean reduction in M.A.O. of 64·8 per cent was achieved by prostaglandin and this is statistically significant ($t = 4{\cdot}37$, $P < 0{\cdot}01$).

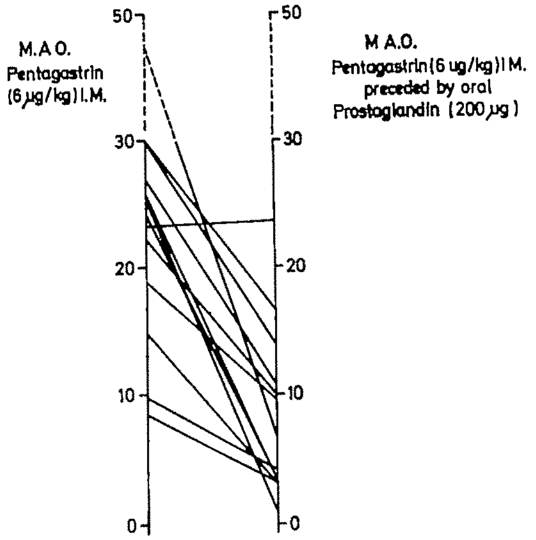

FIG. 5.—Effect of oral administration of 200 µg. of prostaglandin 15(R)15 methyl-E_2 methyl ester on the maximal acid output induced by pentagastrin (6 µg. per kg. i.m).

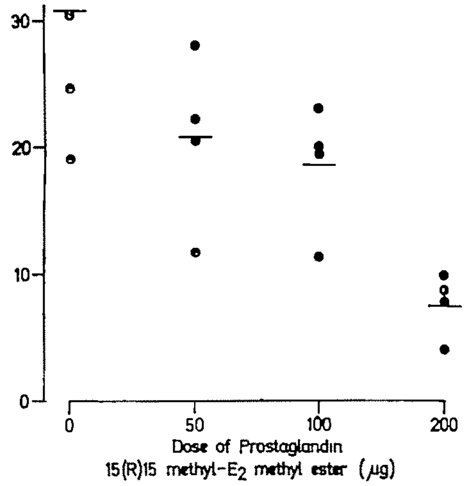

FIG. 7.—Effect of graded doses of prostaglandin 15(R)15 methyl-E_2 methyl ester on the maximal acid output induced by pentagastrin (6 µg. per kg. i.m.) in 4 subjects.

The effect of graded doses of oral prostaglandin on the pattern of pentagastrin-induced secretion is seen in *Fig*. 6, which shows the results of four separate tests carried out in 1 individual. *Fig*. 7 displays the effect of graded doses of prostaglandin on pentagastrin-induced secretion in terms of M.A.O. in 4 individuals each undergoing four separate tests.

DISCUSSION

The synthetic analogue prostaglandin 15(R)15 methyl-E_2 methyl ester is a potent inhibitor of both basal and pentagastrin-induced secretion when given orally to male volunteers. In the case of pentagastrin-induced secretion the inhibitory effect of the analogue is dose-related. On the other hand, bolus intravenous injection of the same 200-µg. dose did not inhibit basal acid secretion to a significant degree. It is therefore probable that the inhibition produced by oral administration results from a direct primary action on the gastric secretory cell rather than from a secondary effect due to peripheral vasodilatation with a consequent reduction in gastric mucosal blood-flow. This is supported by observations in our laboratory that in the dose range employed in the present study the analogue does not affect systemic arterial blood-pressure in male volunteers (Karim, Somers, and Ganesan, 1973). Furthermore, as Jacobson (1970) has demonstrated in the dog, any decrease in gastric mucosal blood-flow observed during intravenous infusion of prostaglandin E_1 is the result rather than the cause of gastric secretory inhibition.

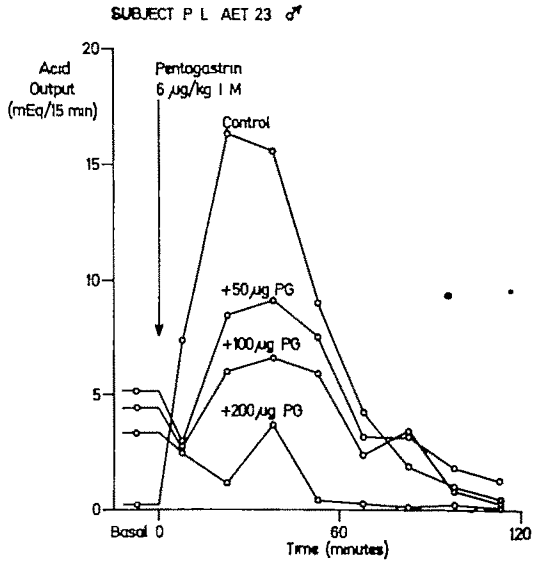

FIG. 6.—Effect of graded doses of prostaglandin 15(R)15 methyl-E_2 methyl ester on the acid output induced by the injection of pentagastrin (6 µg. per kg i m.) in 1 individual.

The inhibition of gastric acid secretion in man by intravenous administration of the naturally occurring prostaglandins E_1, E_2, and A_1 has been previously reported (Classen, Koch, Deyhle, Weidenhiller, and Demling, 1970; Wada and Ishizawa, 1970; Wilson, Phillips, and Levine, 1971). However, the degree of inhibition has been far from impressive and a constant intravenous infusion technique has been necessary for any reduction in secretion to occur. Similarly, attempts to influence human secretion by oral administration of the naturally occurring compounds prostaglandin E_1 and E_2 have not been successful (Horton, Main, Thompson, and Wright, 1968; Karim and others, 1973). The probable explanation for the failure of naturally occurring prostaglandins in this context is their susceptibility to rapid inactivation and metabolism. This process is initiated by the enzyme prostaglandin 15-OH dehydrogenase which is widely distributed in the body. The synthetic analogue prostaglandin 15(R)15 methyl-E_2 methyl ester differs from its parent prostaglandin E_2 in that it is not a substrate for the enzyme and consequently enzymic degradation at carbon 15 is prevented. In view of the fact that prostaglandin E_2 occurs naturally in the human gastric mucosa it is conceivable that the synthetic analogue mimics the physiological role of its parent E_2 compound, differing only in its immunity from enzymic attack. The failure of intravenous bolus injection of the analogue may simply reflect a dilution effect, with a lower ineffective concentration arriving at the parietal cell. If prostaglandin E_2 does enjoy a physiological role in the control of gastric secretion, then interaction with the enzyme adenyl cyclase and inhibition of cyclic AMP formation are potential mechanisms of action suggested by the effect of prostaglandins on other biological systems (Steinberg, 1967; Shaw and Ramwell, 1968).

Whatever the physiological significance of prostaglandin E_2 the synthetic analogue prostaglandin 15(R)15 methyl-E_2 methyl ester must be considered as a compound of therapeutic potential. The sustained inhibition of acid secretion which follows oral administration is now known to extend to pepsin secretion as well (Salmon, 1973), and the alterations are achieved without detectable side-effects on blood-pressure or gastro-intestinal motility. Further indication of the analogue's potential has come from the demonstration of a marked ulcer-sparing effect when administered locally in the Shay rat preparation (Carter, Ganesan, Bhana, and Karim, 1973). If the absence of side-effects is confirmed prostaglandin 15(R)15 methyl-E_2 methyl ester may prove a valuable aid in the management of the peptic ulcer diathesis.

PROPHYLAXIS IN ILIOFEMORAL VENOUS THROMBOSIS

THE MAJOR AMPUTEE AS A CLINICAL RESEARCH MODEL

By D. R. HARPER, D. P. DHALL, and P. W. H. WOODRUFF

ABERDEEN ROYAL INFIRMARY

The clinical evaluation of the effectiveness of various 'anti-thrombotic' agents has never been adequately undertaken owing to the low incidence of clinically significant deep venous thrombosis and, in many instances, the difficulties of its clinical diagnosis. The criteria of high incidence and clinical significance are found in the major amputee, where pulmonary embolism contributes to a high mortality (Eastcott, 1969). That the most important source for such an embolus is from the iliofemoral segment is known (Mavor and Galloway, 1967), and the common problem of stump oedema reinforces this view.

The control series comprised 15 patients who had mid-thigh amputations for obliterative arterial disease. At amputation a cannula was placed in the long saphenous vein and 540 ml. of 0·9 per cent saline were infused over a period of 5–10 days, during which time serial phlebography of the iliofemoral segment was undertaken at intervals via the cannula. Ten patients subsequently developed thrombus in their iliofemoral segments, progressing to complete occlusion in 5 patients. Four of the 15 patients developed pulmonary embolism, 1 of whom died.

The cannula-phlebographic technique not only provides objective confirmation of the incidence and extent of iliofemoral venous thrombosis but also presents the opportunity to study the effect of various 'anti-thrombotic' agents.

A clinical trial with dextran 70 was undertaken using the cannula-phlebographic technique. Six patients received 500 ml. of 6 per cent dextran 70 in isotonic saline immediately after amputation and the same dose on the first, third, and fifth postoperative days. Daily cannula phlebograms revealed only 1 iliofemoral venous thrombosis (in the only patient to have a swollen stump), while in 5 cases there was no evidence whatsoever of iliofemoral venous thrombosis on the amputated side. A further 6 patients were studied in whom the dextran dose was related to body-weight and the fifth-day aliquot was omitted. No patients developed iliofemoral venous thrombosis as shown by cannula phlebography.

It is concluded that dextran 70 used in this way has a highly significant anti-thrombotic action. This confirms in an objective way the previous work *in vitro* and in animal experiments. The question of dosage schedule as well as the effectiveness of the many other 'anti-thrombotic' agents available may now be relatively easily resolved using the cannula-phlebographic technique in the major amputee as described in this investigation.

A REPORT OF THE SYMPOSIUM ON GENERAL SURGICAL TRAINING

By M. R. WILLIAMS
KENT AND CANTERBURY HOSPITAL, CANTERBURY

THE final afternoon at the meeting of the Association of Surgeons of Great Britain and Ireland was devoted to a Symposium on General Surgical Training chaired by Mr. Norman Barrett, Director of Postgraduate Studies of the Royal College of Surgeons of England.

The stage was set by four short papers designed to describe the problems. Following this a panel of eight, including the original speakers, discussed questions from the floor.

Although the principles and problems discussed were relevant to the whole of Great Britain it transpired that most of the examples and all the figures given related exclusively to England, Wales, and Scotland.

Professor Ivan Johnston, Chairman of the Specialist Advisory Committee in General Surgery, explained the constitution of the Joint Committee of the Royal Colleges of Surgeons, which has charged itself with the duty of arranging satisfactory training programmes in all branches of surgery. The Joint Committee will ensure that trainees are ripe for consultant responsibilities 8 years after registration and will recognize their status as successful trainees after completion of their programmes by granting a certificate without examination. Because of the multiple disciplines in surgery, the Joint Committee has set up several Specialist Advisory Committees. In General Surgery, which is relevant to the symposium, the Specialist Advisory Committee consists of six members of the Association (until recently this figure was four), together with six representatives of the Royal Colleges and three representatives of the Association of Professors of Surgery.

The Specialist Advisory Committee in General Surgery has been charged by the Joint Committee with the duty of advising on the principles underlying a sound training in general surgery, and of identifying individual posts which by combination with others are suitable for training programmes. Trainees on completion of the programme should be accredited as being ready for consultant responsibilities.

The Advisory Committee has agreed that the 4 final years of higher surgical training must for logistic reasons be identified with the achievement of senior registrar status, either as National Health Service senior registrars or as lecturers with honorary senior registrar contracts. These programmes, which normally last 4 years, though designed with great flexibility to meet individual problems and opportunities, should expose the trainee to contrasting periods of surgical experience, each being excellent of its kind. In general, programmes should normally involve periods of service in university and district general hospitals during the 4 years, including 1 optional year attached either to an academic department doing research or to a centre providing specialized experience in this country or abroad.

When looking at posts for suitability for inclusion in a recognized programme particular emphasis is laid on their capacity to provide for the trainee adequate clinical responsibility, operative experience, and intimate contact with the trainers, as well as the availability of good investigational facilities.

The approval of programmes is a continuing process and is as yet by no means complete, but so far 182 programmes have been approved in England, Wales, and Scotland; 140 for senior registrars and 42 for lecturers, involving 49 university and 47 district general hospitals. These are the *Category I* posts, the location of which will be published in due course.

While visiting hospitals members of the Committee have become aware that there are several posts which provide training in every way equivalent to senior registrar posts but which for logistic reasons can only be graded as registrar status. Eighty-seven of these posts have so far been identified and placed in a separate category (*Category II*).

It has been agreed by the Joint Committee that a trainee who has held one of these posts can after obtaining senior registrar status apply for retrospective recognition of 1 year of his service in such a post towards his 4 years of higher surgical training, and also that should it be more expedient for a trainee's experience to do so a senior registrar can spend 1 year in such a post during his 4 years' rotation.

To make the most of this flexibility it is essential that each region sets up a General Surgical Training Committee, containing representatives of the university and district general hospitals, the postgraduate dean, and medical administrators, to supervise and to advise individual trainees in their programmes and prospects. Professor Johnston made a special plea that regions which had not already done so should set up such a committee.

Finally, there are numerous posts which provide excellent training either aimed at giving the trainee the experience to obtain his Fellowship or providing increased experience immediately after obtaining it but before he is likely to be able to obtain a post of senior registrar status. These posts providing basic training in surgery in general are of great importance and are complementary to those designated for higher surgical training. They are placed in *Category III*.

Mr. John then made a plea for increased use of the training facilities at district hospitals where 85 per cent of all patients are treated. While 61 senior registrar posts are in district general hospitals compared with 80 in the university hospitals the discrepancy is much greater at registrar level, where the ratio is 513 : 111. Rotation would ensure that the excellent training facilities at registrar level in the district hospitals are fully utilized.

Dr. Elizabeth Shore of the Department of Health and Social Services then discussed the implications of logistics. The position is that while the number of senior registrar posts in general surgery is more or less in step with the anticipated number of consultant vacancies, a considerable imbalance has occurred over the years in two ways. First, the number of consultants per head of population is much higher in some regions, particularly in the south, than in others. In order to correct this the Central Manpower Committee, in whose province this problem now lies, is encouraging differential expansion within the 4 per cent per annum of consultant posts to help the deficient areas, so that eventually the number of consultants in general surgery per head of population should be evened up.

Secondly, the number of registrar posts in general surgery is considerably out of balance with the number of vacancies at senior registrar level; the latter cannot be increased without upsetting the present fairly satisfactory balance with consultant vacancies until the consultant establishment itself has been increased. This applied to many surgical specialities such as gynaecology and orthopaedic surgery. The Central Manpower Committee therefore proposes not to increase the number of registrar posts in these specialities until the consultant establishment has expanded by the planned 4 per cent per annum for several years and there is convincing evidence that the present imbalance between registrar and senior registrar posts has been rectified.

Mr. Birt, Chairman of the Educational Advisory Committee of the Association, discussed the implications. He felt that the interests of the trainees must come first. Rotation through a variety of posts in one good hospital or hospital group met the needs of the trainee before obtaining his Fellowship.

After obtaining his Fellowship and while waiting and competing for a senior registrar appointment the trainee was in great need of adequate guidance and counselling to make the best of his abilities, so that, for example, those who were unlikely to be successful in their ambitions should be diverted to less competitive fields without undue waste of time. This was the function of the Regional Surgical Training Committees and of the trainee's consultants.

It should be recognized that as far as case load and teaching responsibility are concerned the distinction between university hospitals and the larger district hospitals is becoming blurred. Nevertheless, while serving in post-Fellowship (Category III) and higher surgical training (Categories II and I) posts rotation of the trainee between different institutions so as to be influenced by different consultants is desirable. This implies an active surgical training committee to manipulate available rotations in the trainees' interests, and to arrange the provision of good accommodation at each post so as to cause the minimum disturbance of the trainee's family life.

Finally, there is at the moment a discrepancy between the number of posts required to train replacements for consultants retiring and the number required to deal with the service load. This gap can be filled only by increasing the consultant establishment and possibly establishing some non-consultant grade to deal with some of the simpler but time-consuming forms of surgery, such as repair of hernias and excision of haemorrhoids.

In the discussion which followed, various points were raised.

A fear was expressed that training programmes might become too rigid, that individual posts would vary over the years in their training capacity, and that some men who had had unconventional careers, particularly those who had served for a part of their time overseas or in the Services, might have difficulty in breaking into the system.

The Panel in answer emphasized that the work of the Specialist Advisory Committee is a continuing process, with constant modifications. The Advisory Committee would rely heavily on the Regional Surgical Training Committees who could advise them about any posts where training capacity had altered and which should be re-examined. They could also make arrangements to fit in the 'odd man out' as seemed most suited to his needs and abilities.

A similar fear was voiced that it might prove difficult for a surgical trainee to obtain adequate experience in genito-urinary surgery if he wished to offer this as a special interest in his consultant post. The Panel felt there should be no difficulty in seconding such a trainee for a year, or if necessary longer, to a Category II post in a specialist unit during his higher surgical training.

Several speakers felt that trainees at the moment were deficient in training in operative surgery; it was hoped that with the emphasis on rotation to district hospitals where there is a large load of clinical material and good training is available this difficulty would be overcome.

It was suggested from the floor that the logistic gap between the trainee posts and service load could be met by lengthening the senior registrar period to 6 or 8 years, but this did not gain the support of the platform. Professor McColl, emphasizing that security is of great importance to the trainee, described the 7-year programme established in Guy's Hospital and the South-east Metropolitan Region where, subject to satisfactory progress, a trainee is rotated through district and university hospitals and the professorial unit at yearly intervals, progressing automatically from registrar to senior registrar grade.

Finally, the needs of overseas graduates in search of higher surgical training were touched upon. Dr. Shore explained that it was possible to establish supernumerary honorary posts, provided that the holder was financed by his own government and undertook to return overseas and not to apply for established posts in this country.

The Panel felt that certain Category II posts might well be used for this purpose.

Mr. Barrett, summing up, said that clearly the discussion had only skated on the surface of the problems involved in higher surgical training but that he hoped the debate now started would continue.

SHORT NOTES OF RARE OR OBSCURE CASES

ABDOMINOSCROTAL HYDROCELE

BY M. R. TANGA, P. R. AVARADI, AND G. MOHANDAS GANDHI

DEPARTMENT OF SURGERY, HYDERABAD KARNATAK EDUCATION SOCIETY'S MEDICAL COLLEGE, AND GOVERNMENT GENERAL HOSPITAL, GULBARGA, MYSORE, INDIA

SUMMARY

1. Four cases of abdominoscrotal hydrocele presenting within a short span of 5 months are reported.

2. In one of our patients there was associated an incompletely descended testis and this testis had a seminoma. Such an association has not been reported previously. Abdominoscrotal hydrocele may be more common than is generally believed.

SINCE Dupuytren's (1834) first description of abdominoscrotal hydrocele, cases have been frequently reported in the literature. Burkitt and Williams (1964) collected 59 cases from the world literature. From India, Ramakrishnan and Swami (1959), Kaur, Sekhon, and Manchanda (1965), Razdan (1968), and Gupta, Mital, and Razdan (1971) have reported a total of 11 cases of abdominoscrotal hydrocele. We have encountered 4 such cases in a short span of 5 months at the Government General Hospital, Gulbarga. The present report is based on these 4 patients.

CASE REPORTS

Case 1.—A 40-year-old male was admitted to the Government General Hospital, Gulbarga, on 29 Dec., 1971, with a 1-month history of a swelling over the right groin. The swelling was reduced by pressure over the scrotum or on lying down and it increased on walking and on coughing. There was also pain on coughing. The scrotal swelling had gradually increased in size. The patient gave a history of a cough with expectoration of 5 months' duration. There was no history of trauma. He had suffered from guinea-worm infestation 15 years earlier.

There was a right-sided swelling measuring about 12·5 × 10 cm. extending from the scrotum to the right inguinal region. There was no tenderness. His local temperature was normal. There was impulse on coughing. A hard mass was felt in the upper part of scrotal skin, and it measured about 2·5 × 1 × 1 cm. The testis was palpable and normal. A diagnosis of abdominoscrotal hydrocele with calcified guinea-worm was made.

The haemoglobin was 11·5 g. per cent and the E.S.R. was 30 mm. per hour (Westergren). Urinalysis was normal. He was first treated for his cough for 10 days. Operation was performed on 9 Jan., 1972. The approach was via a longitudinal incision over the scrotum. At operation the sac was found to be extending well beyond the deep inguinal ring. The entire sac was excised. The postoperative course was uneventful.

Case 2.—Mr. B., aged 40 years, was admitted on 26 Jan., 1972, with a history of left groin and scrotal swelling of 3 months' duration with pain in the swelling for 1 month. Examination revealed a left inguinoscrotal swelling. The inguinal extension reached the left anterior superior iliac spine. There was visible and palpable impulse on coughing and this was not reducible. The swelling was soft and fluctuation could be elicited between the inguinal and scrotal parts of the swelling. The testis on the left side could be felt vaguely, just below the left superficial inguinal ring. The lower part of the scrotum on the left side was empty.

The patient was found to be anaemic with a haemoglobin of 65 per cent. His E.S.R. was 35 mm. per hour (Westergren). Urinalysis was normal. A diagnosis of left inguinoscrotal hydrocele with an incompletely descended testis was made. At operation about 750 ml. of clear fluid were drained. The testis looked much larger than normal and there was suspicion of malignancy. A left radical orchidectomy was therefore carried out. The complete hydrocele sac was excised and a drain was left in position. The postoperative course was uneventful. Histopathological examination of testis showed seminoma (*Fig.* 1).

Case 3.—Mr. B., aged 25 years, was admitted on 13 Feb., 1972, with a history of right scrotal swelling of 3 years' duration and abdominal swelling of 10 days' duration. The right-sided scrotal swelling had been insidious in onset and slow in progression. The abdominal swelling had also been insidious in onset. There was no pain in the scrotum and lower abdomen, no fever or rigor, and no history of a cough.

Examination revealed a right-sided inguinoscrotal swelling. This swelling was continuous with a suprapubic intra-abdominal swelling, measuring 10 × 12·5 cm. (*Figs.* 2, 3). The skin over the swelling was stretched and shiny. There was visible and palpable impulse on coughing. There was cross-fluctuation between the scrotal and abdominal swellings. A diagnosis of right abdominoscrotal hydrocele was made. The haemoglobin was 70 per cent. Other haematological and urinary examinations were within normal limits. Screening of the chest was also within normal limits.

On 18 Feb. the patient was operated on under spinal anaesthesia. A 7·5-cm. incision over the anterolateral aspect of the right scrotum was made. The sac was exposed and tapped; 2 litres of clear hydrocele fluid were drained. The sac was explored. Superiorly the sac extended up to the umbilicus, laterally it extended to the anterior superior iliac spine, and posteriorly up to the upper border of the sacrum. Partial excision and eversion of the sac were done. A drain was placed. After obtaining perfect haemostasis the wound was closed in layers. The postoperative course was uneventful. At the time of discharge the suprapubic mass which had been felt earlier was absent.

Case 4.—Mr. S, aged 20 years, was admitted on 19 April, 1972, with a history of left-sided scrotal swelling of 18 months' duration and left-sided lower abdominal swelling of 15 months' duration. The onset of the swelling had been insidious. The scrotal swelling tended to disappear in the recumbent position. Six months previously the patient had had high fever with rigors and pain in the abdomen which had subsided after 2 days without treatment.

Examination revealed a left-sided hydrocele which reduced in the recumbent position with the appearance of lower abdominal fullness on the left side. There was visible and palpable impulse on coughing. There was cross-fluctuation between the scrotal and abdominal swellings. An internal inguinal ring occlusion test was negative. Invagination of the finger into the external ring revealed a passage behind the anterior abdominal wall to a big cavity whose periphery could not be reached with the finger. A diagnosis of left abdominoscrotal hydrocele was made. The haemoglobin was 80 per cent and urine examination was normal.

On 22 April under spinal anaesthesia the patient was operated on via an 8-cm. inguinoscrotal incision. The sac was explored and it was found to extend into the abdomen deep to the anterior abdominal wall. The upper limit was at the level of umbilicus, laterally it was limited by the iliac bones, and below by the inguinal ligament. Posteriorly it could be easily separated from the peritoneum, medially it extended up to the midline, and inferiorly the communication with the scrotum was 5 cm. wide. The whole of the abdominal part was excised with eversion of the scrotal part of the sac (*Fig.* 4). The posterior wall of the inguinal canal was repaired as it was found to be weak. The patient had an uneventful post-operative course.

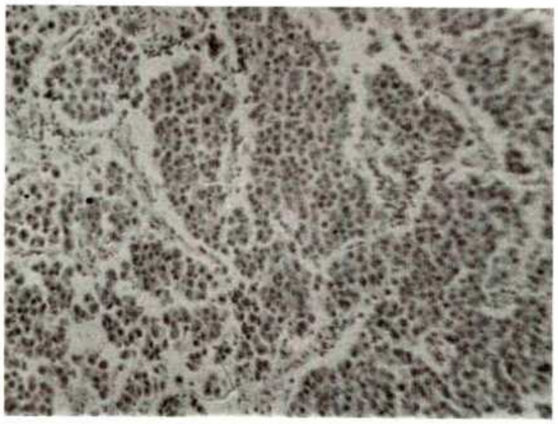

FIG. 1.—*Case* 2. Photomicrograph of seminoma of testis. H. and E. (× 135.)

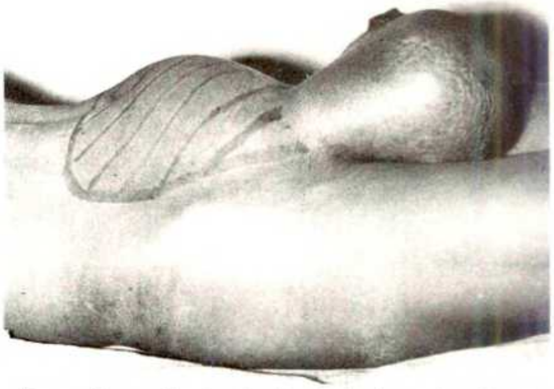

FIG. 2.—*Case* 3. Showing the abdominal and scrotal swellings in continuity.

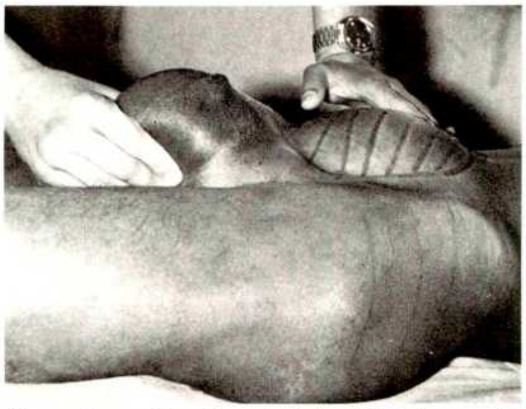

FIG. 3.—*Case* 3. Cross-fluctuation being elicited between the abdominal and scrotal parts of the hydrocele.

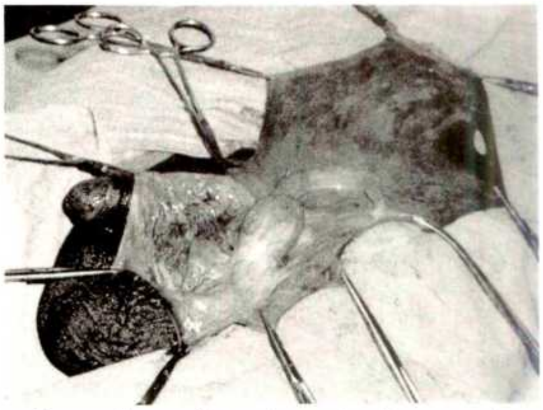

FIG. 4.—*Case* 4. The entire sac has been opened up vertically. The upper part of the sac is the abdominal portion and this has been dissected.

DISCUSSION

It would appear from a review of the world English literature that abdominoscrotal hydrocele is quite rare. In 1964 Burkitt and Williams (1964) could collect only 59 cases from such a review. In India Ramakrishnan and Swami (1959) collected 6 cases from the records of the Madras General Hospital between 1953 and 1958, to which they added 1 case of their own, while during the same period there were 4256 cases of all varieties of hydrocele. Other reports from India are by Kaur and others (1965; 1 case) and Gupta and others (1971; 3 cases out of 1787 cases of all types of hydrocele). However, in a short span of 5 months at the Government General Hospital, Gulbarga, we have encountered 4 cases of abdominoscrotal hydrocele. We are not certain whether this disease is more common in this part of the country or whether it is a mere coincidence that we have encountered several cases in such a short period. The latter reason is the more likely one because in the same unit there was not a single case during the previous period of 2 years.

There are many possible explanations for the occurrence of such a hydrocele. Jacobson (1893) put forward the theory that an infantile hydrocele extends up between the peritoneum and anterior abdominal wall. This is the usually accepted theory, but it is difficult to explain the retroperitoneal extension of this hydrocele. According to Dupuytren (1834) an ordinary tense hydrocele may extend into the abdomen. Dupuytren's theory is supported by Currie (1953) and Burkitt and Williams (1964). If Dupuytren's theory is to be accepted this type of hydrocele should occur more frequently in India since a large percentage of Indians have tense hydroceles for many years, and yet the reported incidence of abdominoscrotal hydrocele in India is very low. A third possible theory was outlined by Cabot (1936), who believed that abdominoscrotal hydrocele occurs as a result of a bottle-neck connexion between the hydrocele of the cord and tunica vaginalis, but this view is not generally accepted.

Abdominoscrotal hydrocele has been given various names by different people. Dupuytren (1834) called it 'hydrocele-en-bissac' and the name 'abdominoscrotal hydrocele' was proposed by Bickle in 1919. Other names which are sometimes used are 'bilocular hydrocele' and 'abdominal hydrocele'. The term 'abdominoscrotal hydrocele' seems to be the most appropriate because it is simple and self-explanatory. Various subvarieties of abdominoscrotal hydrocele are described and these are properitoneal, interstitial, and retroperitoneal, the first type being the commonest. Three of the present cases were of the properitoneal type and 1 case had a retroperitoneal extension. Prather (1942) and Ramakrishnan and Swami (1959) felt that the properitoneal variety is the most usual type, while Gupta and others (1971) stated that the retroperitoneal variety is the commonest. Ramakrishnan and Swami (1959) and Gupta and others (1971) believed that right-sided abdominoscrotal hydrocele is more common than the left-sided type. In the present series there was an equal distribution between the two sides. Prather (1942) also encountered an equal distribution between the right and left sides.

The majority of these patients are asymptomatic except for the presence of the swelling. A few of them have dull pain in the abdomen and scrotum. Very few patients have pressure symptoms or acute abdominal manifestations. Richards (1908) reported frequent micturition due to pressure on the bladder. Litvak's (1958) patient presented with acute abdominal symptoms due to torsion of the upper lobe of the sac on the inguinal neck. Our patients complained of a mass in the groin and abdomen and dull pain in this region. Pain in the region of the swelling could be due to haemorrhage in the sac or an increase in the tension in the sac. Razdan (1968) has described a new physical sign, which he claims is present only in abdominoscrotal hydrocele. This sign constitutes the presence of a prominent skin fold overlying the neck of the scrotal portion and the external inguinal ring. He claims that a similar fold is seen in the photograph of Lord's (1959) patient. This sign was later propagated by Gupta and others (1971) from the same institution but does not seem to be very convincing, at least in our patients.

The majority of abdominoscrotal hydroceles are idiopathic. In some cases they may be secondary to such conditions as epididymitis or epididymo-orchitis. Steele (1875) reported 1 case of abdominoscrotal hydrocele in a patient with an undescended testis.

REVIEWS AND NOTICES OF BOOKS

Allgemeine und spezielle chirurgische Operationslehre. Volume 10, Part 3, **Die Operationen an der Hand.** By W. WACHSMUTH, Würzburg, and W. WILHELM, Aschaffenburg. Pp. 641 + xxiv. Illustrated. 1972. Berlin: Springer-Verlag. DM.590.

THIS volume is one of a series of publications on general and special surgery. The editors, Dr. Wachsmuth and Dr. Wilhelm, are supported by a distinguished group of co-authors, mostly from the Federal Republic but including others with established international reputations. There is a formidable list of contents beginning with general principles, techniques, and armamentarium of hand surgery. Specific subjects discussed in detail include the surgical management of injuries requiring amputation; wounds of the skin including burns, both thermal and chemical; fractures in all regions of the hand and wrist; surgery of the rheumatoid hand; surgery of the peripheral nerves as they affect hand function, including the surgery of pain; injuries to and operations upon muscles, tendons, and vessels; infections; the pathological conditions of contractures of all types, with a large chapter on Dupuytren's contracture. Tumours are discussed and a very full appraisal is given of reconstructive tendon surgery with detailed analysis of techniques and indications. The reconstructive aspects of sensory loss and its restoration are given adequate coverage. A considerable section of the book is devoted to the congenital deformities of the hand and their reconstruction. The subject material covered, therefore, is of an extremely comprehensive nature.

The book throughout is beautifully produced. The illustrations without exception are first class, being lucid and totally understandable. A textbook of this nature must have a place in the libraries of all departments with a special interest in hand surgery and will have particular value for surgeons who are less experienced in the problems of hand surgery but who for geographical reasons may be required to undertake this work.

It is inevitable with a textbook of this nature that comparisons are drawn between it and comparable textbooks in English. This multi-authorship volume containing a great deal of personal experience with a comprehensive bibliography has a definite place in the literature of hand surgery but as a supplement to classic textbooks in this field rather than as a replacement.

The German authors are to be congratulated on the way that they have combined first-class illustrations of surgical procedures with a brief and concise text. It is perhaps inevitable, in view of the tragic German experience in recent years, that a considerable section of this book should be devoted specifically to the problems of the less common congenital abnormalities.

Inevitably there are some criticisms, albeit of a minor nature; thus, the normal techniques of nerve repair are dealt with very briefly while a considerable amount of text and illustration is devoted to the interesting but none the less unproven technique of microscopically assisted nerve-grafting. A similar criticism can be applied to the section on fractures where uncommon techniques are illustrated profusely but there is a lack of emphasis of the simpler and more common management of day-to-day problems. Although the text when looked at carefully goes some way towards detailing indications for the limitless procedures listed, one is still left with the uneasy feeling that the inexperienced hand surgeon might assume that the solution to many problems can only be by complex operative techniques. One would have wished for firmer emphasis on the need for careful case selection. In certain areas the text is not definite enough in emphasizing the fundamental point of the essential simplicity of hand surgery.

These minor criticisms apart, this is a magnificent publication on which the editors and all the authors are to be congratulated most warmly. Unfortunately the combination of the German language and, more importantly, the price may diminish the wide circulation which this book certainly deserves.

Surgery Annual 1972. Edited by PHILIP COOPER, M.D., University of Florida, and LLOYD M. NYHUS, M.D., Chicago. 9¼ × 6½ in. Pp. 445 + xii. Illustrated. 1972. New York: Appleton-Century-Crofts. $17.50.

THIS is a varied and variable volume. There is an excellent review on shock but the treatment of venous thrombo-embolism contains no references to the excellent contributions from the United Kingdom in the past few years. The chapter on peptic ulcer illustrates closure of the duodenum in several illustrations, as well as complementary photography which seems unnecessary in this kind of book. Curiously the references on follow-up after vagotomy omit the papers by Goligher and his colleagues. Chapters on the short-gut syndrome and the significance of ileal resection are complementary and well written, but elsewhere the book is less thorough and the references are sometimes limited and inadequate.

This book is for the library, and most British surgeons will consult it there.

Thoracic Surgical Management. Fourth edition. By J. R. BELCHER, M.S., F.R.C.S., London Chest Hospital, and M. F. STURRIDGE, M.S., F.R.C.S., London Chest Hospital. 8¼ × 5½ in. Pp. 192, with 60 illustrations. 1972. London: Baillière Tindall. £2·20.

THE production of a fourth edition of this book is sufficient recommendation of its value. It is an excellent manual containing practical information of use not only in thoracic surgery but also in the postoperative chest complications of general surgery. In this edition the section on cardiac surgery has been brought up to date.

The illustrations are clear line drawings which are easily understood. Trivial criticisms might include the omission of the use of an Argyll tube for intercostal drainage and scant reference to needle lung biopsy in the investigation of pulmonary lesions. This book is thoroughly recommended as essential for all surgical residents in general as well as in thoracic units and its price is extremely modest.

Problems in Paediatric Urology. Edited by J. H. JOHNSTON, M.B., F.R.C.S., F.R.C.S.I., Liverpool, and R. J. SCHOLTMEIJER, M.D., Ph.D., Amsterdam. 9½ × 6½ in. Pp. 301. Illustrated. 1972. Amsterdam: Excerpta Medica. $27·50.

THE pace of advance and the speed with which opinions change are perhaps most noticeable in the specialized but important field of paediatric urology. Here fashions in treatment change with a rapidity which bewilders those not closely involved in the subject. Only a short time ago it seemed correct to revise the bladder neck for stenosis; now we are told that it is the distal urethra which is so often stenosed. Sometimes conservative treatment of reflux is advocated, and on other occasions reimplantation is favoured. For those who want to keep abreast of this rapidly advancing field, Johnston and Scholtmeijer offer an excellent series of essays by acknowledged authorities in their own subjects. They have selected some of the more important and controversial topics. Hardy Hendren details his method of the surgical reconstruction of megaureter, without perhaps emphasizing how difficult this operation is. The diverse problems posed by ureterocele and ectopic ureters are described equally clearly by Johnston, and Innes Williams reviews his great experience with the surgery of vesical exstrophy, giving due emphasis to its associated and very important pathological conditions. In a characteristically sparkling attack, O'Donnell demolishes the current muddle-headed thinking which governs so much of what is done and written about childhood urinary infection—this review is a pleasure to read, no less outstanding for its prose than for its common sense. Memorable also is John Scott's account of bladder-outflow obstruction, and the chilling description of the urological aftermath of meningomyelocele from Zachary and Lister would make any reader ponder yet again the ethical dilemma posed by this difficult problem. Scholtmeijer reviews the current preoccupation with the distal urethra of little girls and seems to agree with the present fad for curing enuresis by splitting the urethra to an acceptable norm of capaciousness. This chapter certainly requires one to exercise some willing suspension of disbelief, but at least the reader is given the evidence and can draw his own conclusions.

Surgeons, paediatricians, and urologists in training will find this a clear and useful book which throws a lot of light on this important scene.

Clinical Anesthesia. Volume 9, Part 1, **Management of Patient for Radical Cancer Surgery.** Edited by WILLIAM S. HOWLAND, M.D., and OLGA SCHWEIZER, M.D., New York. 10 × 7 in. Pp. 162 + xi. Illustrated. 1972. Oxford: Blackwell Scientific Publications. £5.

THIS volume is the first section of the ninth part of the 'Clinical Anesthesia' series. It deals on a very broad front with the major problems that face the modern anaesthetist in radical cancer surgery. As the editors rightly point out in the introduction, the type of anaesthetic agent itself is of least importance in such cases, and the book therefore concentrates chiefly on subjects relative to disturbances in surgical physiology. Chapters on fluid balance, blood replacement, venous pressure monitoring, and shock are well presented with commendable correlation between basic physiological principles and clinical application. This volume will be of especial value to the postgraduate student of anaesthesia.

Die medizinische Rehabilitation der Querschnittsgelahmten. By I. KOCH, Berlin. 8½ × 5½ in. Pp. 141. 1972. Berlin: Veb. Verlag Volk und Gesundheit. 17.50M.

THIS paper-back monograph reports on some 300 patients with paraplegia who have been treated in a special rehabilitation unit in Berlin since the Second World War. The methods of treatment and the results achieved are compared with the various series reported in the world literature and it becomes clear that the facilities available in Berlin are inadequate to deal with the increasing number of patients with traumatic paraplegia.

This report should be of interest to all those involved in the care of paraplegic patients, but English-speaking readers are warned that because of the excessive use of abbreviations throughout this monograph it is a difficult book to read.

Klinisch Gastroenterologie, Volumes 1 and 2. Edited by L. DEMLING, Erlangen. 10½ × 7½ in. Vol. 1, pp. 546 + xix; Vol. 2, pp. 635 + xxviii. Illustrated. 1973. Stuttgart: Georg Thieme Verlag. DM.298.

THESE two closely packed volumes deal with current thoughts on a variety of topics in the diagnosis and treatment of gastro-intestinal disease.

The text is in German, but the authors are from many different parts of the world, although the majority are European. It is an excellent book of its type, drawing together the present concepts of disease in the alimentary tract. Depending on the author, some chapters have an emphasis on topics of surgical interest, but it is more a book for the specialist in gastro-enterology.

As a textbook for the specialist or a reference book it provides a concise and readable text which should make it a standard work available in the library.

Textbook of Surgery. The Biological Basis of Modern Surgical Practice. Tenth edition. Edited by DAVID C. SABISTON, jun. M.D., Durham, North Carolina. 10 × 7 in. Pp. 2135 + xxvii. Illustrated. 1972. London: W. B. Saunders Co. Ltd. £11·70.

SURGERY is now divided into so many sub-specialities that no individual can possibly keep up to date with more than a fraction of the current knowledge. This book, the tenth edition of the Davis-Christopher *Textbook of Surgery*, is one of the few which provides a truly encyclopaedic coverage of the whole field of modern surgery. It would therefore be a useful acquisition for anyone involved in surgical work, be he undergraduate, trainee, consultant, or teacher.

The theme of this book, made explicit in its subtitle, is the biological basis of surgery. The first 400 pages comprise 19 chapters on fundamental principles and problems applicable to all surgical practice, such as wound healing, the metabolic response to trauma, renal failure, etc. There follow 100 pages on transplantation and then 1600 pages on systematic surgery. Each chapter gives a satisfactorily complete account of the scientific and clinical aspects of its subject, but the prospective reader should not expect to find great emphasis on such problems as surgical judgement, differential diagnosis, and minutiae of operative technique. Most chapters are embellished with an historical introduction, and another special and helpful feature is a brief synopsis of key references. There are 142 contributors but the style and format are reasonably uniform. It is a pleasure to see Mr. Alan Parks as one of only two contributors from outside the North American continent.

This book is moderately expensive in absolute terms but is none the less excellent value as a basic and comprehensive reference work. With over 2000 pages it is a little cumbersome, but it can be purchased in two volumes which would be easier to handle.

Progress in Pediatric Surgery, Volume 5. Edited by P. P. RICKHAM, M.D., M.S., F.R.C.S., D.C.H., Liverpool, Professor W. CH. HECKER, München, and Professor J. PRÉVOT, Nancy. 9 × 6 in. Pp. 161. Illustrated. 1973. Berlin: Urban & Schwarzenberg. No price given.

THIS is the fifth in a series of reviews of progress in paediatric surgery and it follows the principles and maintains the standards of the previous numbers. The purpose of the series is to provide the opportunity for a rather fuller presentation, analysis, and discussion of current problems than is possible in the restrictive pages of surgical journals. Many editors look with more favour on contributions which occupy 3 or 4 pages than on those which need 10 or 12, and there must be few editors who could face with equanimity the prospect of publishing a volume in which the contributions ranged between 22 and 52 pages.

This volume has a very varied selection of articles and includes an extensive survey of hydatid disease from the paediatric surgical team in Marseilles, a topic which in these days of rapid travel must be of wider concern than previously. There is an excellent account of the experimental work on intestinal anastomosis by Herzog of Basel, demonstrating a technique which, although somewhat intricate, is likely to produce an anastomosis which is more secure in the early and late phases and less constrictive than any of the standard methods.

The contribution by Kathel from the Paediatric Surgical Department in Liverpool presents two aspects of isotope renography. The first part is concerned with the use of the analogue computer to quantify the isotope renograms in a series of older children and this is followed by a short account of the prognostic value of a qualitative renography which is applicable to neonates and has been used with success in the assessment of the neurogenic bladder.

Mollard and Paillot present what might be regarded as a typically French lucid and logical analysis of primary mega-ureter in children, describing in particular the presentation and management of the obstructive and non-obstructive types as well as the refluxing and non-refluxing primary mega-ureters; this is a very useful analysis. Pompino and his colleagues from the Department of Paediatric Surgery in Munich have attempted to confirm the reports of some Russian investigators that re-innervation of the neurogenic bladder is possible by the application of an isolated but innervated and vascularized loop of ileum to the surface of the bladder after the mucosa of the ileum has been removed. This careful experimental study showed no evidence whatever of innervation crossing from the intestine to the bladder.

This series has proved the value of a vehicle for the publication of the unusually long, the unusually complex, or even the unusual paper which might contribute to progress in paediatric surgery.

Urologische Operationen; Atlas zur Indikation, Technik, Nachbehandlung. Edited by GEORGES MAYOR and ERNST J. ZINGG, Zürich. 11½ × 8½ in. Pp. 659 + xii. Illustrated. 1973. Stuttgart: Georg Thieme Verlag. DM.298.

THIS is a new atlas of urological surgery. Both of the editors and most of the authors are Swiss. The book specifically excludes the problems of urological surgery in relation to gynaecology, paediatric urology, and transurethral procedures. The emphasis of this well-produced volume is on operative techniques, which is illustrated by many excellent half-tone diagrams, but peroperative and postoperative complications are stressed and discussed in the text. The book contains many excellent chapters, but the one dealing with surgery of urethral strictures is somewhat outdated and the management of hydronephrosis has received relatively little attention. For a book of this size the number of references given is rather small, and to the British reader this volume is unlikely to be worth £42.

Alexander's Care of the Patient in Surgery. Fifth edition. By WALTER F. BALLINGER, M.D., St. Louis, JACQUELYN C. TREYBAL, R.N., St. Louis, and ANN B. VOSE, R.N., B.S.N., M.S., St. Louis. 10 × 7 in. Pp. 905 + xvi. Illustrated. 1972. London: Henry Kimpton. £8·65.

THIS book is for all personnel employed in an operating-theatre suite, and as such provides a basic reference for patient care from a technological aspect. The book is well planned and provides informed comment on theatre administration, preoperative preparation of the patient, and details of most surgical procedures. The diagrams are very good and show the principal anatomical structures encountered at different stages of an operation. In addition it illustrates and names the majority of surgical instruments that are in current clinical use.

Although there are inevitably some differences in surgical practice across the Atlantic, this in no way detracts from the main objectives of this book. Its contributors are experienced theatre personnel who describe systematically basic surgical techniques. Each operation is defined, the indications for surgery are listed, the position of the patient is discussed, and both the instruments and sutures likely to be used are itemized.

This book fills an important gap for the theatre nurse who is not only interested to provide more than the correct instrument at the right time but also keen to understand operative technique and to anticipate the requirements of the surgeon.

Zentrale Storungen der Temperaturregulation. By Professor Dr. GERHARD LAUSBERG, Giesen. 9 × 6 in. Pp. 168, with 68 illustrations. 1972. New York: Springer Verlag. DM.80.

THIS is a monograph on disturbance of the temperature-regulating mechanism. Following a review of the literature the writer reports in detail his investigations on 238 patients with neurosurgical conditions or head injury, together with suitable control subjects on whom he performed experiments of raising or lowering the environmental temperature and recording essential parameters.

The book has an extensive bibliography and each chapter has a long English summary. This volume will undoubtedly be of great interest to physiologists and research workers but is rather outside the scope of the average neurosurgeon.

Thyroid Tumours, Lymphomas, Granulocytic Leukemia. Edited by M. FIORENTINO, R. VANGELISTA, and E. GRIGOLETTO. 9½ × 7 in. Pp. 210 + xii. Illustrated. 1972. Padova: Piccin Medical Books. L.8000.

SCIENTIFIC communication where a multidisciplinary subject such as oncology is concerned is obviously an important problem to solve. One good solution is holding workshops and seminars devoted to specific aspects of oncology where interested laboratory and clinical workers meet together for full discussions, and the proceedings are published later for the benefit of those not present. This particular seminar in Padua was concerned with the three important, but different, subjects of thyroid tumours, lymphomas, and granulocytic leukaemia. Fifty contributors from seven countries took part in the seminar.

The subject-matter of the section on thyroid tumours follows the usual pattern of pathology, epidemiology, and treatment with the presentation of results. Here we still have much to learn, for carcinoma of the thyroid is not one disease but many; this is highlighted on the first page, where the point is also made that the majority of tumours arise from the follicular cell and the minority from the parafollicular (C) cell, the tumours of the two groups behaving quite differently. The risk of women being affected is almost double that of men, but the tumours in women seem to be of lesser malignancy. The aetiological factors provide much food for thought, and include the importance of ionizing radiation, where the high incidecne of tumours in children in the United States is contrasted with that in Western Europe. When planning treatment the importance of studying the character and behaviour, including histology, of each tumour is rightly stressed. Consideration is given to radiotherapy as a prophylactic following surgery where excision has been incomplete, and for inoperable disease. In the latter group survival rates of 17 and 8·5 per cent at 5 and 10 years respectively are cited, and external radiotherapy is stated to be especially effective in medullary carcinoma. The tumour dose should be 5000–6500 rad to an adequate target volume. Preliminary data also showed the value of radio-isotope therapy for inoperable disease.

The discussions about chronic granulocytic leukaemia reveal its seriousness and the inadequacy of present therapy. The position regarding Hodgkin's disease is much better, however, for important advances have occurred in our understanding of this disease, including more precise histological diagnosis and staging, better clinical evaluation, and combined therapy with adequate supportive treatment. This is reflected in a marked improvement in prognosis. In the pathological staging of untreated patients with lymphoma, laparotomy and splenectomy are essential so that accurate therapy can be planned. There are also reports indicating that after splenectomy patients can tolerate larger amounts of radiotherapy and chemotherapy. An important point is made that diagnostic laparotomy provides an opportunity to transpose the ovaries from the radiation field, which is so important for pre-menstruating and menstruating females. The value of combined drug therapy is now accepted in achieving both complete and long remissions.

This volume contains many references for further reading, and whilst the text is in English there are additional sections of summaries and conclusions in Italian. There are many oncologists who will study this book with both interest and profit.

Blutgerinnung und Operation. By Professor Dr. ERWIN DEUTSCH, Wien. 9¾ × 7 in. Pp. 66 + vi. Illustrated. 1973. Berlin: Urban & Schwarzenberg. DM.19.80.

THIS monograph on blood coagulation and surgery was previously published in volume 5 of Breitner's *Surgical Textbook*. The physiology of the clotting mechanism is described in detail and the various tests available to diagnose the different diseases and conditions which interfere with normal blood-clotting are all described. The second half of the volume is devoted to the actual problems of practical surgery in patients with various clotting defects and the management is described in detail. There is a useful index and an extensive bibliography, and the book should be of particular interest to haematologists who are involved with surgical units.

Chirurgischer Ratgeber. By R. SCHROTH, Wittenberg. 7½ × 4¾ in. Pp. 315. Illustrated. 1972. Berlin: Veb Verlag Volk und Gesundheit. 19.80M.

THIS is a pocket book outlining most aspects of general surgery especially in relation to diagnosis and emergency treatment. The little book is full of sound advice and is illustrated by simple line diagrams.

The book contains 400 key sentences which are clearly marked and which summarize the important diagnostic or technical points, especially in relation to life-saving measures. Weekly or monthly medical journals might be well advised to copy and translate some of these key sentences and publish them as 'thoughts for the week'.

Oxygen Supply. Edited by M. KESSLER, D. F. BRULEY, L. C. CLARK, jun., D. W. LÜBBERS, I. A. SILVER, and J. STRAUSS, Dortmund, Germany. 9½ × 6½ in. Pp. 312 + xii. Illustrated. 1973. Berlin: Urban & Schwarzenberg. DM.78.

THIS is a report of a workshop on oxygen supply to the tissues and on oxygen, hydrogen, and enzyme polarography. The meeting was held in Dortmund in July, 1971, and was organized by D. W. Lübbers and M. Kessler. The 54 papers included in this volume were grouped into four sessions. The first session dealt with the theoretical

They'll be glad you're using Dexon* sutures

Children, especially, suffer from loneliness when mother, father, brothers or sisters are in hospital.

Surgeons who use Dexon* sutures have reported that certain patients can be discharged from hospital several days earlier than when conventional sutures have been used. This means an earlier return home for the patient and a quicker end to loneliness for those waiting at home.

Dexon* The everybody benefits suture

EDITORIAL NOTICES

Original articles or reviews are invited and editorial communications should be addressed to the *Editorial Secretary, British Journal of Surgery, c/o John Wright & Sons Ltd., Bristol, BS8 1EX.* Articles are accepted on the understanding that they are contributed to this Journal only, and that articles and their illustrations become the property of the Journal unless the authors state, before publication, that they reserve the right to themselves. Each article should be accompanied by an adequate summary, suitable for publication. Authors are asked to ensure that original illustrations are securely packed and adequately protected.

REPRINTS can be supplied at a reduced price if authors indicate their requirements at the time that proofs are returned. The following scale will be helpful as a guide to the cost; 50 copies are suggested as a minimum number.

NO. OF PAGES	NUMBER REQUIRED							
	50	100	150	200	250	300	400	500
2	£2·83	£3·70	£4·27	£5·70	£5·69	£6·32	£7·74	£8·99

An extra 16p per 300 pages will be charged for reprints sent to outside the United Kingdom.

An additional charge will be made for reprints containing coloured illustrations, depending upon the amount of extra work involved.

BUSINESS COMMUNICATIONS should be addressed to *John Wright & Sons Ltd., British Journal of Surgery, Bristol, BS8 1EX.* Remittances should be made payable to *The British Journal of Surgery.*

BINDING.—Handsome Cloth Cases may be obtained for binding Vol. 59. Case 70p post free; Case and binding £2·75, post free. Cases are also available for some of the earlier volumes. Applications should be made to the Publishers, who will also undertake the binding if desired.

BACK NUMBERS.—The Publishers would be glad to purchase copies in good condition of Nos. 1, 3, and 8, Vol. 51; No. 9, Vol. 53; No. 10, Vol. 54; and Nos. 11 and 12, Vol. 55.

ADVERTISEMENTS.—All communications should be addressed to *H. S. Janes & Partners (Publications) Ltd., St Martin's House, 159 Clapham High Street, London, SW4 7SU* (telephone 01-622 9225).

INSTRUCTIONS TO AUTHORS

PREPARATION OF MS.—Papers should be submitted in typescript and the author should retain a carbon copy. Double spacing should be used throughout, except for quotations.

TABLES AND ILLUSTRATIONS.—Tables should be numbered in roman numerals and set out on sheets separate from the text. Illustrations, too, should be kept separate from the text and should be numbered consecutively in arabic numerals. Each figure should be referred to in the text, and the descriptive legends should be typewritten on a separate sheet of paper, and not put on the backs of the originals. Glossy photographs should be supplied unmounted and positive prints (not X-ray films or lantern slides), also unmounted, should be sent whenever possible. Drawings should be in a finished state suitable for reproduction. When *coloured illustrations* are submitted as colour prints they should be accompanied by the actual transparencies where possible. As coloured illustrations are very expensive to reproduce, the author may on occasion be asked to make a contribution towards the cost.

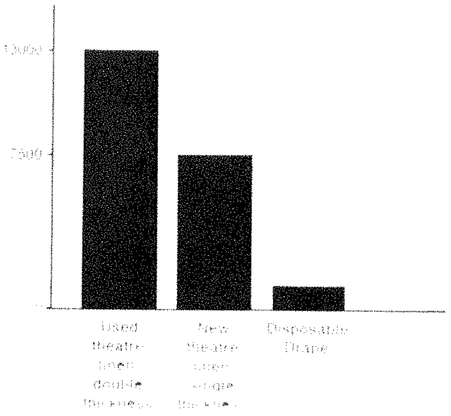
The quiet Revolution

1973·72·71

The change began over two years ago, as the result of an extensive programme to develop a system superior to traditional balloon cloth drapes.

The primary requirement was that the drape fabric should resist "strike-through" of moisture and thus bacteria– a risk associated with the use of balloon cloth over 20 years ago[1]



BACTERIAL PENETRATION OF SURGICAL DRAPING

Average number of bacteria per one square centimetre in one minute

BARRIER* fabric was created tough but soft, and is made into specially designed drapes for *all* areas of surgery.

The Seward Identikit...

Every stainless steel Lloyd-Davies' Sigmoidoscope made by Seward has components which are absolutely identical – guaranteed interchangeable.

And that's an immense advantage when a lot of these instruments pass through the CSSD together. Because you never need to label any parts, or worry about 'matching up'.

Which saves time. Cuts losses.

You'll probably agree, the Seward Lloyd-Davies' Sigmoidoscope* is good news.

Well, here's some more.

The Seward St. Mark's Proctoscope*.

Made entirely of stainless steel. With all parts absolutely identical – guaranteed interchangeable.

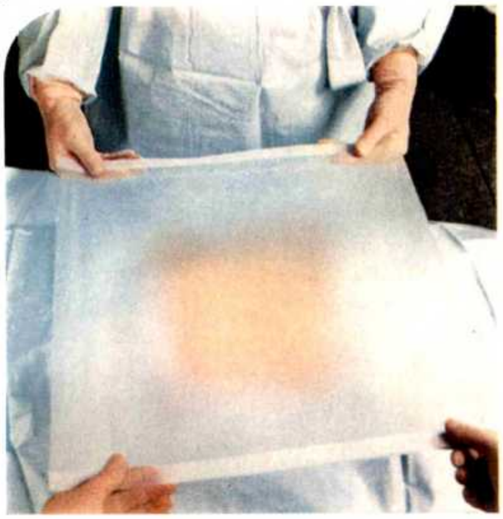
The new BARRIER* Incise Drape



BARRIER* Incise Drapes used with disposable or traditional drapes.

BARRIER* Incise Drapes in use with the BARRIER* Theatre Drape System.

The transparent drape with clear advantages

BARRIER* Incise Drapes are effective – film elasticity and the specially developed High Tack adhesive ensure adhesion at the edge of the incision even during heavy retraction and manipulation.

BARRIER* Incise Drapes are supplied sterile – the pack's heavy board reinforcement protects the sterile drape from puncture damage, and its Fibre Tear seal gives immediate visual proof of seal integrity and improves aseptic handling.

BARRIER* Incise Drapes give greater control – wide control tabs that give positive control of the drape and help prevent 'self-adhesion'.

BARRIER* Incise Drapes emphasise safety – they are glare free and inherently static safe while providing a smooth surface for organs temporarily displaced during a procedure.

Pennywell Industrial Estate, Sunderland, England SR4 9EW.

Today we introduce the Valleylab system-and tomorrow TUR will be easier.

Easier because the solid state Valleylab SSE2 offers the hard-pressed surgeon a major breakthrough in diathermy.

Easier because the Valleylab SSE2 has isolated patient circuitry which means that the current flow is immediately reduced to a negligible level if the patient cord is broken or disconnected or if the patient plate is not in place.

Easier because the Valleylab SSE2 weighs less than 30lbs and takes up less vital room than any competitive system.

Easier because the Valleylab SSE2 has all the power, all the reliability of bigger, bulkier systems.

Make TUR easier for you–contact Polystan, the U.K. distributors, for more details.

UBRETID®
distigmine bromide

maintains smooth muscle tone
prevents urinary retention or intestinal atony

UBRETID inhibits cholinesterase for a full 24 hours, giving prolonged improvement in smooth muscle tone. Thus, with minimum inconvenience to staff or patient, a normal pattern of micturition and defaecation can usually be re-established without the discomforts of catheters or enemata. Where indwelling catheters are unavoidable, **UBRETID** will maintain bladder tone, reduce residual urine volume and encourage normal bladder function when the catheter is withdrawn.
Full details of **UBRETID** ampoules and tablets are available upon request.

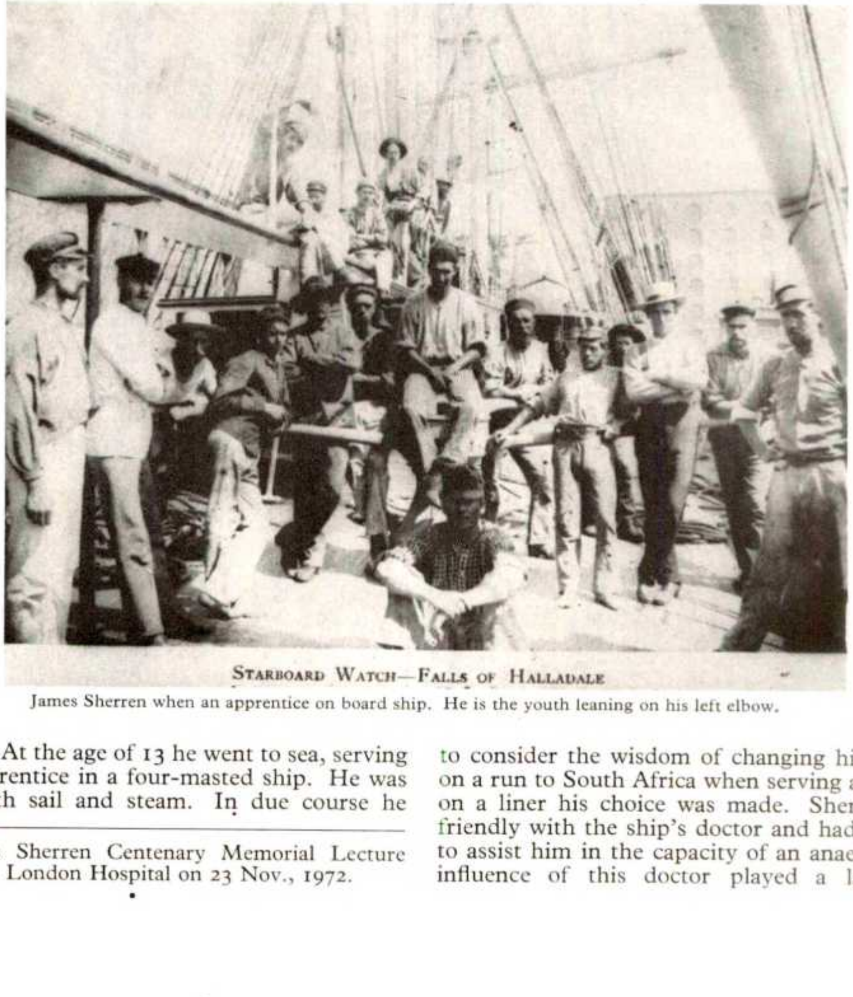
JAMES SHERREN—SURGEON AND SAILOR*

By A. M. A. MOORE
CONSULTING SURGEON TO THE LONDON HOSPITAL

JAMES SHERREN was born at Weymouth in 1872, just one hundred years ago. He was the son of John A. Sherren, a Justice of the Peace, who was a printer and publisher and a pillar of the Methodist Church. He was educated at Weymouth College. Early in his life he showed a great love of the idea of becoming a sailor and was very conscious that the sea has ruled our destinies. At the age of 13 he went to sea, serving first as an apprentice in a four-masted ship. He was trained in both sail and steam. In due course he obtained his master mariner's certificate (as Frederick Treves had done before him). He was 21 years of age at the time.



James Sherren when an apprentice on board ship. He is the youth leaning on his left elbow.

One can imagine that even in those early days he possessed an unusual determination and strength of character. Repeated attacks of malaria contracted at Delagoa Bay in Portuguese East Africa caused him to consider the wisdom of changing his calling, and on a run to South Africa when serving as chief officer on a liner his choice was made. Sherren was very friendly with the ship's doctor and had on occasions to assist him in the capacity of an anaesthetist. The influence of this doctor played a large part in persuading him to take up medicine. So began a career which was to enrich surgery.

---

* The James Sherren Centenary Memorial Lecture delivered at the London Hospital on 23 Nov., 1972.

In May, 1894, Sherren entered the London Hospital as a student. It must have been difficult for one who had spent so many years at sea to take up studies in this new field, but he stuck to it and had a brilliant student career. He was awarded the prize in anatomy and physiology and in his final year gained scholarships in medicine and obstetrics.

James Sherren at the height of his career.

He was greatly influenced by the consultants under whom he worked. He served as clinical clerk to Sir Stephen Mackenzie and Dr. Gustav Schorstein, and as a dresser to Mr. Mansell Moullin and Mr. H. P. Dean, and to Sir Frederick Treves and Mr. Jonathan Hutchinson, junior. All these are famous names in the London Hospital's history. Sherren passed the Primary Fellowship of the Royal College of Surgeons in 1897 while still a student, and qualified in 1899.

After qualification he served as house physician to Dr. Sanson and Dr. F. J. Smith, whose portrait hangs in the Club's Union, house surgeon to Mr. Hurry Fenwick and Mr. Roxborough, receiving room officer, and finally junior and then senior resident accoucheur. When holding this last appointment he was President of the Residents' Mess. When he was junior resident accoucheur his senior was Dr. Cecil Wall, who later was to be the distinguished physician on the consultant staff of the London Hospital.

In 1900 he passed the Final Fellowship of the Royal College of Surgeons of England. His parents presented him with a suitably inscribed gold watch to celebrate his success. Early in 1901 he was appointed surgical registrar at the same time as Henry Newland, who was later to be the first President of the Royal Australasian College of Surgeons. Sir Henry Newland, as he became, used to visit the London Hospital frequently in later years. I first met him at the centenary meeting of the British Medical Association in 1932 when I was Sir Henry Souttar's registrar. In December, 1902, at the age of 30 James Sherren was appointed to the surgical staff of the London Hospital as assistant surgeon on the retirement of Mr. Waren Tay, the famous general surgeon and ophthalmologist whose name is remembered as one of the describers of Tay–Sachs disease. This was 8½ years after he had started as a medical student, a most remarkable record. At the same time in 1902 he was appointed surgeon to Poplar Hospital, which at that time was closely associated with the London Hospital, and surgeon to the Stanmore Cottage Hospital.

He quickly showed his soundness of judgement and technical skill and the fact that he could tackle almost any surgical problem.

For some years he served as a demonstrator of anatomy and of surgical pathology, and from 1903 to 1911 he lectured on elementary clinical surgery.

In 1908 he was joint editor with Sir Robert Hutchinson of the *Index of Treatment* published in Bristol.

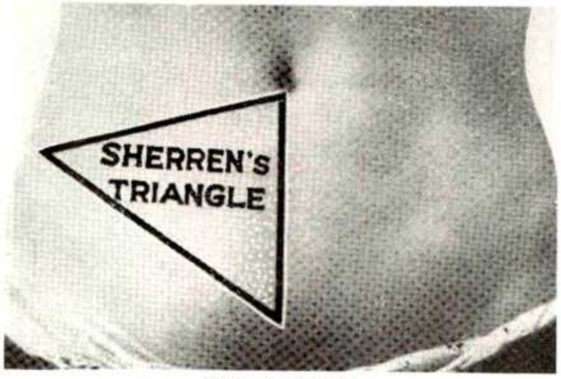
James Sherren did pioneer research work with Sir Henry Head, the brilliant neurologist, on the peripheral nervous system, and in 1908 published a *Monograph of Injuries of Nerves and Their Treatment*. In the First World War injuries of nerves were studied with great care. Much of this work was based on Sherren's monograph. The observations of Head, Rivers, and Sherren upon the nature of cutaneous sensation and its division into various types of sensitivity was derived from a study made upon the division of a cutaneous nerve in Head's forearm. This was done by Sherren. They described two sorts of sensitivity, namely, one of a delicate discriminatory sort (epicritic) and another of a vague coarse type of sensation (protopathic). Head and Sherren investigated the sensory qualities of the gastro-intestinal mucous membrane. They showed that ice-cold water and water at 50° C. introduced directly through gastrostomy and colostomy openings would give rise to sensations of cold and warmth usually in the region of the umbilicus. They finally concluded that the oesophagus and anal canal are always sensitive to heat and cold, the stomach rarely so, and the colon to a very limited extent.

They believed that most pain in visceral disease is referred and not direct. Head and Sherren showed that the afferent fibres running with motor nerves when stimulated by pressure cause pain and painful contractions of muscles. In peritonitis the nerves themselves are directly affected by the inflammation of the parietal peritoneum. This is the cause of the widespread rigidity of the abdominal wall in diffuse peritonitis. Sherren made a special study of the prognosis and treatment of brachial plexus, birth injuries, and the so-called Erb–Duchenne paralysis. He considered that the prognosis is on the whole favourable, but that unless improvement is evident within 3 months of delivery complete recovery is rare.

Albert John Ochsner, who had been born in Wisconsin and claimed to be directly descended from Vesalius, was Professor of Clinical Surgery in the

University of Illinois. In 1902 he published a *Handbook of Appendicitis*, in which he advocated the delayed treatment of this disease. At the same time Sherren championed the cause of the delayed treatment of appendicitis in this country and trained his assistants in its principles. In the *Practitioner* of June, 1905, he wrote: 'If we are able to see a case within the first 24 to 36 hours when the disease is probably limited to the appendix, operation should be performed and the appendix removed. After this most favourable time has passed I am strongly of the opinion that if possible we should wait until the attack is over and remove the appendix in a quiescent period in three months' time.' He emphasized that this method of treatment, which has come to be known as the Ochsner–Sherren régime, must only be undertaken in a hospital with a fully staffed theatre available at all times in case the patient's condition showed signs of deteriorating and an operation had to be undertaken without delay.

Sherren's description of the appendix triangle, which is outlined by lines joining the summit of the iliac crest, the pubic tubercle, and the umbilicus, refers to an area of skin hyperaesthesia met with in obstructive appendicitis and indicates that the appendix is distended and may burst at any moment. This is a certain indication for immediate surgery. This observation was one of the outcomes of the research he had carried out with Sir Henry Head on the problem of cutaneous hypersensitivity in visceral disease.



Sherren's triangle.

With the passage of time Sherren became more and more interested in abdominal surgery. At first he was a follower of Sir Frederick Treves who had performed the first properly recorded appendicectomy in the London Hospital in 1887, but on the early death in 1908 of Harold Barnard, a surgeon of the highest promise who had written the classic description of subdiaphragmatic abscess, Sherren decided to confine himself largely to abdominal surgery, which was then a rapidly growing speciality, and he quickly made an outstanding reputation.

His predominant surgical interest became the treatment of duodenal ulcer. This condition had first been treated by Codivilla in 1893 by the operation of gastrojejunostomy. During the early years of this century this procedure was developed in great measure by Moynihan, W. J. Mayo, and Sherren.

It is interesting to record Sherren's own description of the operation written in 1911:—

> 'The abdomen should be opened by displacing the right rectus muscle. The ulcer is usually found on the anterior surface of the first part of the duodenum. The peritoneum over it presents a speckled reddish appearance and a definite induration can be felt between the examining finger and the thumb. There may be adhesions binding the duodenum to the gall bladder and liver. In every case the appendix and gall bladder should be examined and treated if necessary. After examining the stomach for signs of ulcer, a posterior vertical no loop gastrojejunostomy should be carried out. That this is sufficient in most cases is shown not only by the long series recorded in which absolute relief of symptoms occurred, but by demonstration at a second operation performed later for some other condition.'

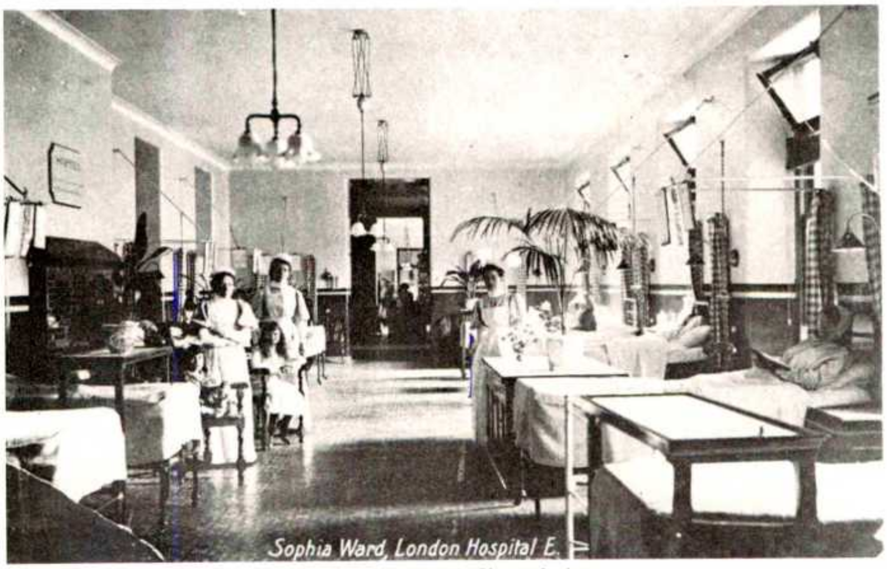
Sir Frederick Treves in his earlier years.

This operation was generally regarded at the time as giving extremely good results. Shortly before his retirement Sherren reported 537 cases of duodenal ulcer that he had operated on with 10 deaths. At about the same time Moynihan reported 563 cases with a mortality-rate of 0·53 per cent, and at the Mayo Clinic in the period 1914–19, 2734 cases were recorded with a mortality-rate of just 1 per cent.

In 1921 Sherren published a series of lectures on the stomach and duodenum, and was responsible for the chapters on the stomach and duodenum in Choyce's *System of Surgery*.

In addition to numerous operative procedures, Sherren devised a retrocolic anterior gastrojejunostomy of special use in relieving the symptoms in cases of inoperable carcinoma of the stomach. Donald Balfour of the Mayo Clinic made much use of this procedure.

Sherren's success as an abdominal surgeon created a great impression on the medical profession all over the world. His very distinguished colleague Sir Robert Hutchison, later to be President of the Royal College of Physicians, on whom he had successfuly operated for a duodenal ulcer, spoke of him in these words: 'He was, perhaps with the exception of Moynihan, the best abdominal surgeon of his day, and not a few of his colleagues owed much to his care and professional skill.' I am grateful to Sir Peter Hutchison, Sir Robert's son, for this helpful information. He confirms his father's high regard for the professional ability of Sherren and mentions that in 1907 his mother and Mrs. Sherren used to go for carriage drives together when they were expecting their first babies.



Sophia Ward as it was in Sherren's time.

Amongst his junior colleagues who had developed the greatest regard for him was Russell Howard, who in time was to become one of the most distinguished surgical teachers this country has produced. Sherren was an excellent diagnostician and a meticulously careful surgeon. His punctuality was proverbial and if he was due at the London Hospital at 2 p.m. the hall porter clocked him in at 1.59 p.m. with the greatest regularity. As a student I can remember waiting in the front hall for his arrival. He would step out of his car, walk into the front hall, shake hands with his registrar and house surgeon, and then, followed by the firm, walk to the staff room where he put on a white coat and emerge to commence his ward round in Sophia Ward just after 2 p.m. He expected his dressers to be exactly on time for all his ward rounds. I must quote from a letter from Dr. William Evans who was on his firm. He says: 'My old chief was a brilliant operator and never once late for an appointment whether to meet his equals or his betters or his humble dressers.'

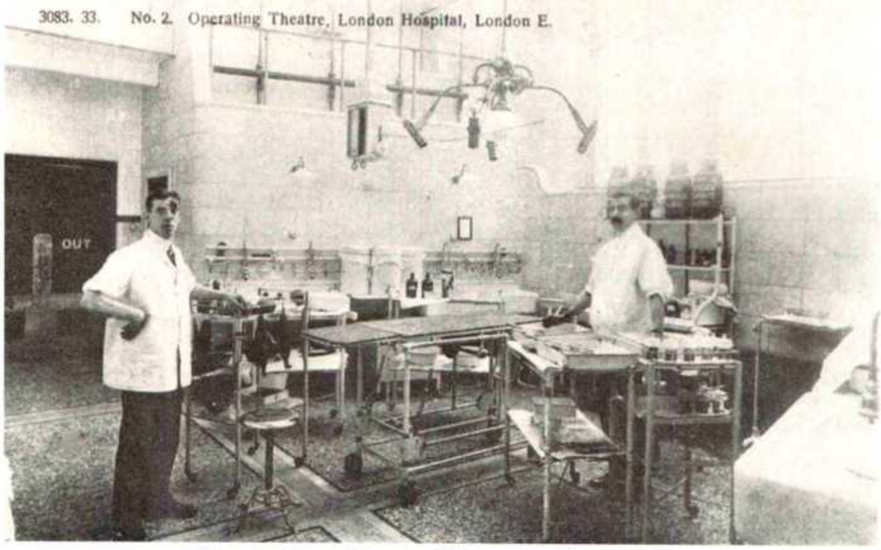
James Sherren was frequently consulted by Miss Eva Luekes, a remarkable woman who was Matron of the London Hospital for 39 years, on the problems of the training and education of the student nurses, matters in which he was intensely interested. For many years he was Surgeon to the Nursing Staff and performed numerous operations on our nurses. At this time sick nurses were admitted to Upper Wards, and the Sister in charge had the intriguing idea of getting every nurse that Mr. Sherren had operated on to embroider a special scarf with her initials. This scarf was presented to Mr. Sherren on his retirement. After his death it was given to the London Hospital where I was able to trace it in the Archives.

At the Royal College of Surgeons Sherren played a very active part. In 1906 he was Erasmus Wilson Lecturer in Surgical Pathology and in 1909 he became an examiner in anatomy for the Primary Fellowship examination. In 1917 he was elected to the Council of the College. In 1920 as a Hunterian Professor he delivered a lecture on: 'Late results of the surgical treatment of chronic ulcers of the stomach and duodenum'. This lecture was published in the *Lancet* on 27 March, 1920. He served as a member of the Court of Examiners from 1921 to 1923 and in 1925 was Bradshaw Lecturer. His subject for this lecture was 'Gastro-jejunostomy'. This lecture was also published in the *Lancet* on 14 Nov., 1925. Mr. Sherren was elected Vice-President of the College in 1925 and 1926. In the University of London he served as an examiner in surgery for the final medical degrees and for the Mastership in Surgery. He was also a member of the Senate of the University.

During the First World War he served with the rank of Colonel in the Army Medical Service as a consultant surgeon attached to the War Office, as surgeon to the King George Military Hospital and to the King Edward VII Hospital for Officers, and as consulting surgeon to the Yarrow Military Hospital at Broadstairs. In 1919 he was honoured by being made a Commander of the Most Excellent Order of the British Empire.

At the summit of his career when he had become a full surgeon to the London Hospital his private practice was enormous. He practised at 6 Devonshire Place and most of his private operating work was done at Fitzroy House which was almost his own nursing home. His numerous famous private patients included Sir Pelham Warner, the eminent cricketer, who referred to him with great gratitude in his biography.

Sherren was a man who owed his advancement to sheer ability and strength of character. For many years whenever he operated his theatre would be crowded with visiting surgeons from abroad, particularly from the United States of America, who had come to witness his great technical skill. It was at this time, before green operating kit had become popular, that Sherren gave instructions that the dressers on his firm should wear green caps in the theatre so that he could easily recognize them when he was operating and direct questions to them. These caps were changed to blue after some years.



3083. 33. No. 2. Operating Theatre, London Hospital, London E.
OUT

Operating theatre No. 2 that Sherren worked in at one time.

Sherren had greatly impressed Lord Knutsford, that greatest of all hospital chairmen and affectionately known as the 'Prince of Beggars', who presided over the hospital's destiny from 1896 to 1933. I well remember when I was a junior student seeing Lord Knutsford and Mr. Sherren walking along a corridor arm in arm in deep and earnest conversation.

Amongst his many gifts Sherren was an accomplished violinist. Sir James Walton, who had been his registrar and on whom the mantle of Sherren descended, spoke of him in the following terms: 'As a chief Jimmy Sherren, as he was affectionately known, was a little frightening but very invigorating. Slackness and slipshod work were intolerable to him and he did not mind saying so. But he liked to be stood up to and respected the sharp retort. In the conventional sense he was ambitious, but his ambition was not of the selfish kind. He wanted the work he was responsible for to be done supremely well. There was a burning zeal about the way he worked and there was something inspiring about that restless, incredibly efficient small man with the sailor's rolling gait.'

He was unceasing in his search for truth. One of his distinguished colleagues has said that it was when he became to know him socially that he realized that there was a great humility about him, coupled with a streak of kindliness which he was very reluctant to show.

It must always be remembered that this great surgeon was working in the days before the discovery of penicillin and the other antibiotics, and he did not have the benefits of modern anaesthesia, pathological and radiological investigations, and the advances in blood transfusion.

In 1926 at the height of his career when he had gained a reputation not only in Britain but throughout the civilized world which he shared only with Lord Moynihan of Leeds, Finisterer of Vienna, and Balfour of the Mayo Clinic he suddenly decided to retire.

Sir Henry Souttar has described the dramatic fashion in which he took his leave of the London Hospital: 'One afternoon when he had finished his operating list, he took off his gloves and said to his senior theatre technician, Macgowan: "Well, goodbye, that was my last operation." He shook hands with everyone in the theatre and then, having changed in the surgeon's room, he went down in the lift alone.

'In the front hall waiting for him was Sir Ernest Morris, the House Governor, the only man who knew that he had resigned, holding his hat and coat. The hall porter came forward to turn off his light on the board, but Sherren waved him away, stood for a moment looking at his name, and then himself turned off the switch. He shook hands with Ernest Morris, and then left the scene of his surgical triumphs for ever.'

Within a few days of resigning from the staff of the London Hospital he left the Council of the Royal College of Surgeons. Sir Hugh Lett, later to be President of the Royal College of Surgeons, was elected to his vacancy on the Council.

Just as he had entered the London Hospital he left it dramatically. What the overwhelming urge was no one knows. Probably he felt again the call of the sea and was determined to answer it while still of an age to enjoy it.

I personally have no doubt that Mr. Sherren had had in mind the idea of returning to the sea as a ship's surgeon for a long time; a possible factor that may have influenced him was the 20-year rule that was in force at the London Hospital at that time. As far as I can determine he became a senior on a firm in 1911. This meant that he would have to retire from the staff in 1931, after 20 years as a senior, at the age of 59 years of age. He may have felt that it would be difficult to start a new life as a ship's surgeon at this age and this may have led him to decide to retire 5 years earlier at 54.

He could leave surgery with the satisfaction of knowing that seldom, if ever, had any man accomplished so much and advanced so far in the short 30 years or so that he had devoted to it.

Returning to his country home overlooking Poole Harbour he found that even here he was unable to rest on land, and so within a few months of retiring from the London Hospital staff, he went back to the sea as a ship's doctor, where he was able to do much to better the conditions of the marine medical service. He served as a ship's surgeon for the P. & O., the Orient, and the Cunard lines until shortly before the outbreak of the Second World War.

Soon after my own appointment to the consultant staff of the London Hospital in 1934 the staff gave a dinner at the old Langham Hotel in honour of Mr. Sherren, who had just returned from a trip to Australia as a ship's surgeon. My memory of him at this time was that he was a very impressive-looking man with a fine head of white hair and a fresh complexion.

In his speech replying to the toast of his health he told an amusing story. Shortly before the liner entered port he was called to see an elderly wealthy lady in her cabin. He gave her some advice about her abdominal trouble. She was loath to accept this. 'Doctor,' she said, 'thank you for seeing me, but I think I will wait until we land when I will consult a proper specialist.' It happened that the local medical association had heard that the ship's doctor of the incoming liner was the world-famous surgeon, James Sherren. They sent a deputation on board to welcome him and he was seen receiving them on the deck by the lady patient who was being taken on shore by stretcher. On inquiring she was told who the ship's doctor really was. As soon as she was settled in a nursing home she sent him a message of apology for her unwitting discourtesy, and begged him to call on her. He did so the next day, taking her a bunch of flowers.

He told of another amusing incident when he was summoned to see a lady patient in her cabin. It turned out that she was an old private patient who had paid him a large fee for an abdominal operation in London. She was indignant to find that after all he was only a ship's surgeon. His closing years were lived at White Barn, Broadstone, in Dorset, where he was able to indulge in his hobby of sailing and his favourite relaxations of golf and playing the violin.

During the Second World War he served on the staff of the local hospital and he died on 29 Oct., 1945, 2 days before his birthday, after a long illness, at the age of 73.

And so passed a figure memorable in the long story of the London Hospital. His life had been full, active, and varied, during the course of which he had earned the respect and admiration of all with whom he had worked and the real affection of his friends.

While Britain breeds such men her position in surgery remains assured.

PHYTOBEZOAR AFTER VAGOTOMY WITH DRAINAGE OR RESECTION

By A. M. MIR and M. A. MIR
DEPARTMENT OF SURGERY, PAHLAVI HOSPITAL, TEHRAN UNIVERSITY, IRAN

SUMMARY

Two cases of bezoar formation after vagotomy and drainage are reported. A review of the literature reveals the stomach to be the most common site of bezoar formation after operations involving vagotomy, whereas most bezoars occurring after gastrectomy are found in the small intestine. The reasons for this difference are discussed, as well as the clinical features and treatment of bezoar.

THE word bezoar comes originally from 'pad-zahr', a Persian word meaning anti-poison. The reason for this terminology is that in primitive communities the solid masses found occasionally in the stomach of goats or other animals were accredited with magical healing, invigorating, and even youth-restoring properties. In man these masses are generally composed of densely entangled vegetable fibres (phytobezoar) or hair (trichobezoar).

Quain (1854) was the first to report an example of phytobezoar formation in an apparently healthy stomach, and there have been many subsequent reports of similar cases. In recent years several descriptions of bezoar formation after gastrectomy have suggested that this is a relatively specific complication of gastric resection (Ward-McQuaid, 1950; Norberg, 1961; Hollander, 1965; Olivier, Prévost, and Rettori, 1966; Cain, Moore, and Patterson, 1968; Pollard and Block, 1968; Vernon, 1969). In most of these patients the bezoar was found in the small intestine; for example, Olivier and others (1966) referred to 50 phytobezoars after gastric resection, 48 of which were in the small intestine.

The preponderance of bezoars in the small intestine after gastrectomy may be explained as a consequence of rapid emptying of gastric contents. Bezoars consist of a thick and concentrated chyme which is inadequately mixed and contains indigestible fibres of vegetable origin. In some patients the bezoar is in the gastric remnant, when a faulty anastomosis may be the aetiological factor.

Vagotomy with drainage or resection has been practised with increasing frequency for more than 20 years for the treatment of duodenal ulcer. Reports concerning the formation of phytobezoar after these operations are relatively recent. Olivier and others (1966) reported the first case of phytobezoar in a patient who had undergone vagotomy for recurrent ulcer after a previous gastric resection. Moseley (1967) published the first case of phytobezoar after vagotomy and pyloroplasty. The bezoar was discovered 2½ months after the operation.

Between 1963 and 1971 at the Pahlavi Medical Centre, Tehran University, we have performed 300 vagotomy and drainage procedures for the treatment of duodenal ulcer. Two cases of phytobezoar occurred after such a procedure.

CASE REPORTS

Case 1.—A 41-year-old man who had been submitted to vagotomy and gastro-jejunostomy for duodenal ulcer in February, 1967, remained well for 2 years, but in March, 1969, he was readmitted for cramp-like pains in the epigastrium of 1 month's duration. Barium-meal examination showed a perfectly patent anastomosis without any marginal ulcer. The stomach contained no residual fluid and the patient was discharged after being given some dietary advice. Four months later, i.e., 2½ years after vagotomy and gastro-jejunostomy, the patient was admitted again as an emergency with acute intestinal obstruction. The patient had suffered from subacute intestinal obstruction for 2 months, terminating in the acute episode. In spite of distension a sausage-shaped lump could be felt in the right iliac fossa. At laparotomy the small intestine was distended, and at about 60 cm. from the ileocaecal valve a hard sausage-shaped mass, 14 cm. long and 6 cm. in diameter, was felt in the lumen of the ileum. It was extracted by an enterotomy and was found to be a hard bezoar composed of unrecognizable fibres tightly entangled together. The gastrojejunal anastomosis was patent without any anastomotic ulcer. The duodenal ulcer had healed. The patient's postoperative course was uneventful. There was no history of any regular or frequent consumption of special fruits or vegetables. The patient left the hospital in a healthy condition. Since then he has been followed up as an out-patient; he remains well and there are no signs pointing to the formation of a new bezoar. He has been advised to avoid uncooked vegetables.

Case 2.—A 45-year-old man underwent vagotomy and gastrojejunostomy for duodenal ulcer in October, 1966. The postoperative course was satisfactory and the patient was in good health for 6 months. After that period he started complaining of vague abdominal pains accompanied by food and biliary vomiting. These symptoms persisted intermittently with varying intensity for nearly 2 years. Medical treatment gave only temporary relief. In November, 1969, i.e., 3 years after vagotomy and gastrojejunostomy, the patient was readmitted as an emergency with acute intestinal obstruction of 12 hours' duration. At laparotomy the duodenum and the first loops of the jejunum were distended. Some 20 cm. below the duodenojejunal junction a hard sausage-shaped lump, 12 cm. long and 4 cm. in diameter, was felt in the lumen of the jejunum. It was found to be a bezoar which was extracted by an enterotomy. It was formed of vegetable fibres stuck tightly together. The gastrojejunal anastomosis was patent without any anastomotic ulcer. The duodenal ulcer had healed. The patient's postoperative course was uneventful and the patient was discharged in a satisfactory condition. He has been followed up for 6 months as an out-patient. There has been no symptom pointing to the formation of a new bezoar.

REVIEW OF LITERATURE

We have reviewed the literature on bezoar formation after vagotomy with drainage or resection (*Table I*), and, including the 2 cases presented here, have found 22 cases. In 17 of these, the bezoar was in the stomach, in 3 it was in the small intestine, and no information about the site was given in the remaining 2 patients.

DISCUSSION

Aetiology.—After gastric resection the majority of bezoars are found in the small intestine (Olivier and others, 1966), probably because of the rapidity of gastric emptying. This is in striking contrast to our finding that after vagotomy operations bezoars are most commonly found in the stomach. It may be presumed that this is related to the effect of vagotomy on gastric motility, and it is therefore of interest that Kuiper (1971) described a bezoar in the stomach of a patient with generalized myotonic dystrophy which he attributed to gastric retention.

Vagotomy has two important effects on the stomach:—

1. Decreased secretion of hydrochloric acid with a reduced peptic activity contributing to thickening of the gastric contents.
2. Decreased gastric motility so that the stomach is an atonic bag with a more or less flaccid antrum which does not accomplish its mixing, grinding, and propulsive actions effectively. Drainage procedures, i.e., gastrojejunostomy or pyloroplasty, or limited resections sometimes fail to relieve these disturbances of motility. This failure is because the motor disturbances of the stomach following vagotomy are occasionally so serious that it is not able to empty its contents adequately, even through a large and patent anastomosis. Slow emptying can also be due to narrowing of the anastomosis. Prolonged retention of food in a slowly emptying stomach, especially if the food contains large amounts of indigestible vegetable fibres, facilitates the formation of a bezoar. Gastritis resulting from retention of food produces an abundant quantity of gastric mucus, which enhances bezoar formation. The resection associated with vagotomy is often of limited extent and may include no more than the gastric antrum. The motor disturbances caused by vagotomy are probably more serious in the distal part of the stomach so that the more limited the resection is the worse the gastric retention may be.

Clinical Picture and Diagnosis.—The site of a bezoar determines the clinical picture. It is worth

noting that a bezoar in the stomach may be completely symptomless and has been found in 3 patients submitted to routine postoperative radiographic examination (Szemes and Amberg, 1968). More interesting still is the fact that in some patients the surgical removal of the bezoar or successful medical treatment leading to its dissolution has not eliminated all the symptoms attributed to the presence of the bezoar (Benoit, Fays, and Hoeffel, 1971). It seems that many of the symptoms are in fact nothing more than the signs and symptoms of delayed gastric emptying.

When the bezoar is located in the stomach the patient suffers from early satiety, a gradual onset of epigastric fullness, especially of a postcibal type, nausea, and vomiting. Emaciation and weight-loss due to malnutrition follow. The bezoar in the stomach sometimes produces a ball-valve mechanism; it causes intermittent obstruction of the anastomosis leading to severe gastric retention and then is suddenly disimpacted to allow gastric evacuation.

In the majority of the patients the bezoar has been discovered by radiographic examination (*Table I*). The characteristic radiological findings are well described by Szemes and Amberg (1968) and Rigler (1970). Barium-meal examination shows one or more spherical masses in the stomach around which the barium flows readily. Careful examination will show that the mass is movable and not attached to gastric mucosa. A delayed radiograph reveals some residual barium covering the surface or imprisoned inside the bezoar. A plain radiograph taken in the upright position sometimes shows the dome-shaped superior surface of the floating bezoar contrasting with the gastric air-bubble.

Treatment.—When the bezoar is in the small intestine the patient presents the picture of acute intestinal obstruction, and emergency laparotomy should be performed in all cases. An attempt should be made to fragment or to squeeze the bezoar gently into the caecum. According to Vernon (1969) this procedure is successful in 38 per cent of cases. Removal of the bezoar by enterotomy should be performed if these measures fail.

The treatment of a bezoar in the stomach is never an emergency surgical procedure. The case should be treated conservatively at first and this is often successful. A phytobezoar is formed of vegetable fibres with a small quantity of protein and much gastric mucus. It is possible to disorganize the bezoar by the administration of papain, a powerful proteolytic enzyme, which acts in an acid as well as in an alkaline medium. Experience has shown that papain is more efficient when used in association with sodium bicarbonate. According to Sanderson, Ibberson, and Fish (1971) this is because sodium bicarbonate is a mucolytic substance which splits the mucus involved in the formation of the bezoar and facilitates the action of papain on the protein constituent of the bezoar. Some authors advise the use of ananase, another proteolytic enzyme. Pollard and Block (1968) proposed the administration of a mixture of enzymes, such as pepsin, pancreatic enzymes, cellulase, and dehydrocholic acid, of which cellulase seemed to be the most effective. Schlang (1970) advocated the use of a solution containing 15 ml. of acetyl cysteine in 50 ml. of normal saline instilled into the stomach three or four times. Some authors, including Sanderson and others (1971), have had good results with intensive gastric lavage. Rigler (1970) advised a liquid regimen and reported 2 patients in whom this treatment was successful in dissolving the bezoar in 2 weeks. These conservative measures are not sufficient to dissolve the bezoar completely in all cases, but may make it smaller or fragment it sufficiently to be vomited or eliminated via the intestine. When conservative treatment proves successful the patient should be advised to avoid unripe fruits and uncooked vegetables. Adequate chewing and proper dietary management prevent the recurrence of the condition in many cases but not in all (Sanderson and others, 1971).

Failure of conservative treatment or frequent recurrences after successful treatment require operation for removal of the bezoar and, if possible, correction of the factor which led to its development. In planning operative treatment it is worth noting that owing to long-standing malnutrition the majority of these patients are in a poor general condition and sometimes are a poor operative risk. Corrective operations have two objectives:—

1. Reconstruction of a new anastomosis if it is defective.

2. More extensive resection of the distal part of the stomach whose motor function is most affected by vagotomy. This should be followed by a gastrojejunal anastomosis.

A NEW VENOUS THROMBECTOMY TECHNIQU

By P. E. KIELY*

VETERANS ADMINISTRATION HOSPITAL, LONG BEACH, CALIFORNIA

SUMMARY

This paper describes a new technique whereby a specially designed thrombectomy catheter can be passed distally in the venous tract without trauma to or hindrance by the venous valves. The catheter is advanced distally on the end of a guide-wire which has been threaded proximally along the vein to be thrombectomized. The technique enlarges the scope of surgery in relation to deep-vein thrombosis. A possible use in arterial thrombo-embolectomy is discussed.

THE use of balloon catheters for removal of intravascular thrombus is well established (Edwards, Sawyers, and Foster, 1970; Mavor, Galloway, and Karmody, 1970; Fogarty, Daily, Shumway, and Krippaehne, 1971). However, thrombectomy of the venous tree presents a technical difficulty not encountered on the arterial side, i.e., the venous valves interfere with distal passage of the catheter. Thus, although an arterial catheter may readily be passed from the groin to the ankle it is not possible to do this in the venous tract. Despite the flexible tip of the venous thrombectomy catheter and other manœuvres recommended to negotiate the valves (Fogarty and Krippaehne, 1965) the farthest distally the catheter can usually be advanced is to the popliteal fossa. At times the valves in the femoral vein cannot be negotiated and venous thrombectomy in the lower limb is then confined to the iliofemoral segment and the superficial femoral vein is ligated (Browse, 1970; Mavor, 1971).

This paper describes a technique of lower-limb venous thrombectomy which makes it possible to clear the main deep veins of thrombus as far as the lower third of the leg. For this purpose a guide-wire is introduced into the deep veins above the ankle and advanced to the groin. Then a specially designed thrombectomy catheter is fitted end to end to the tip of the guide-wire (*Fig.* 1) and passed distally. The guide-wire leads the catheter through the valve commissures.

In principle and in practice the technique has proved to be simple and effective. Following a detailed study in cadaveric limbs the technique has been applied in the clinical condition of extensive whole-limb deep-vein thrombosis. In these instances distal passage of the catheter and thrombectomy have been achieved without difficulty. In particular, no snagging in valves was encountered.

TECHNIQUE

With the patient systemically heparinized the common femoral vein is exposed through a vertical groin incision and its branches controlled. A venotomy is made and a standard iliofemora
is carried out.

To achieve distal thrombectom
materials are needed: (1) a 0·024-in. S
100 cm. in length, of medium flexib
core; (2) a disposable guest cannula,
Braunula or a 19G Butterfly needle,

In this instance before disconnecting the 'line' a tight Esmarch bandage is applied to the limb in an attempt to squeeze thrombus from the branches into the main deep veins. This thrombus is then brought out after removal of the bandage.

The peroneal veins are less accessible than the posterior tibial veins. Although they can be approached through the same medial leg incision the exposure is limited, especially in a swollen leg. A better but still limited exposure of the peroneal veins is afforded by a lateral leg incision diametrically opposite the medial one at the anterior border of the soleus muscle. The posterior compartment is entered, the transverse crural fascia incised, and the flexor hallucis longus fibres detached from their fibular origin throughout the length of the incision. When this muscle is retracted away from the fibula the peroneal vessels are brought into view from under the medial aspect of this bone. There are no suitable branches for the introduction of the guide-wire and therefore direct peroneal venepuncture is necessary. Otherwise the technique of thrombectomy is the same as for the posterior tibial veins, with a further application of the Esmarch bandage before disconnecting the peroneal 'line'.

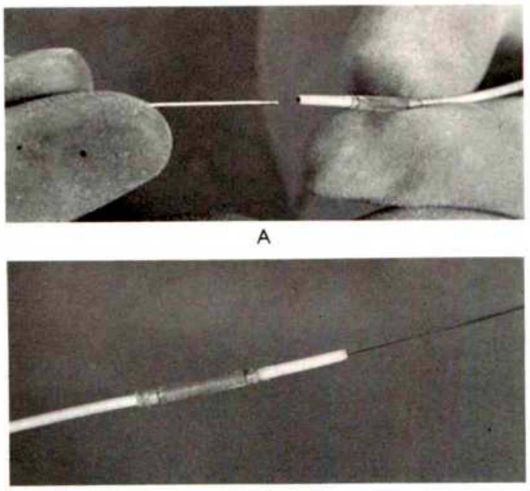

Fig. 1.—A, The specially designed, tapered, open-ended thrombectomy catheter about to be fitted on to the end of a 0·024-in. diameter guide-wire. B, The catheter connected to the guide-wire.

Although in practice it has not been found necessary, it is advisable to have alternative 0·024-in. diameter guide-wires available, e.g., one of soft flexibility or a J-shaped guide-wire with a movable core. Should passage of the straight, fixed-core, medium-flexibility guide-wire be obstructed this could be replaced with one of the alternative types indicated above. Such guide-wires have been found to be enormously effective in negotiating irregular and tortuous arteries and ought readily to pass up the smooth straight venous tract. It would be unwise to use the J-shaped guide-wire without prior proximal control of the femoral vein because of the danger of dislodging thrombus. In addition, with this guide-wire the core should not be withdrawn until the tip has reached a vessel of sufficient diameter to accommodate curling of the tip, i.e., the popliteal vein.

RELEVANT ANATOMY

There are some anatomical facts relating to the superficial femoral vein which need to be mentioned.

While there is usually one main channel there are accompanying medial and lateral comitans femoral veins of varying size. These join the superficial femoral vein below the profunda and as they also communicate with the popliteal vein the guide-wire may side track through one of these vessels only to reappear in the common femoral venotomy (*Fig.* 2A). This was observed in one cadaveric limb. Unrecognized in the clinical situation it could have meant failure to thrombectomize the main femoral vein. Awareness of the possibility and failure to produce the expected amount of thrombus should alert the operator to check that the guide-wire is traversing the main superficial femoral vein. If it is not, the guide-wire should be withdrawn and reintroduced if necessary using a different entry vessel. In this situation the J-shaped guide-wire may also be useful.

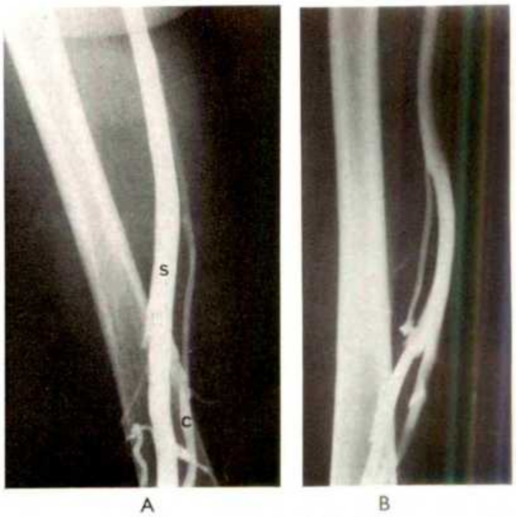

Fig. 2.—A, A phlebogram of the thigh showing a secondary femoral vein (c) coursing beside the main superficial femoral vein (s). B, A phlebogram of the thigh showing loops at the lower end of the superficial femoral vein.

There may be a loop on the femoral vein (*Fig.* 2B). It is quite likely that both limbs of such a loop can be successfully cleared especially when repeated passage of the guide-wire is undertaken.

Operative radiographic facilities are likely to be helpful, as in iliofemoral thrombectomy (Mansfield, 1972). In addition, a suction autotransfusion-linked system would be a valuable adjunct.

USE IN ARTERIAL THROMBECTOMY

When an arterial thrombectomy catheter is passed distally into the leg via a femoral or popliteal arteriotomy there is no control over which of the leg vessels it enters. Because of the angle of take-off the anterior tibial artery is by-passed. As the peroneal artery is the most direct continuation of the popliteal artery it is a common route taken by the catheter in the leg. It is likely that in a significant number of cases thrombectomy of the posterior tibial artery is not achieved. Consequently it is a recommended procedure to expose the posterior tibial artery at the ankle and perform an anteriotomy to achieve clearance from below. The technique described here is an alternative in this situation. The posterior tibial artery is exposed, and the guide-wire is introduced and threaded up the arterial tree to receive the thrombectomy catheter. Once the catheter has entered the posterior tibial artery the guide-wire is disconnected and removed so that the catheter can be advanced beyond the site of arterial puncture to achieve complete thrombectomy.

Acknowledgements.—I should like to thank Mr. Lawson Lyon of Eschmann Brothers & Walsh Ltd., for his invaluable assistance in producing the thrombectomy catheter. I am grateful to Professor G. W. Taylor for his helpful advice, and to the staff of the Department of Medical Illustration, St. Bartholomew's Hospital, London.

EXTENSIVE CERVICAL LAMINECTOMY

LONG-TERM RESULTS

By D. H. R. Jenkins

DEPARTMENT OF TRAUMATIC AND ORTHOPAEDIC SURGERY, UNIVERSITY HOSPITAL OF WALES, CARDIFF

Summary

It has been possible to follow up 5 patients who underwent complete cervical laminectomy for cervical spondylotic myelopathy between 12 and 17 years ago. The operation was described by Rogers in 1961. Clinical examination findings, together with the radiological appearances, indicate that this procedure does not predispose to instability of the cervical spine. This relatively simple procedure achieved long-lasting improvement in the patients examined.

Extensive cervical laminectomy in the treatment of cervical spondylotic myelopathy was described by Rogers in 1961. An attempt has been made to follow up the 33 cases described in his paper, from 12 to 17 years after their original operations.

Full records were available in 21 cases. It is assumed that the remaining 12 cases had undergone operation at establishments other than the major hospitals in the Cardiff area. A postal search revealed that 5 of the 21 patients had died from unknown causes and 3 had died from malignant disease which may or may not have been related to the underlying factor in their spondylotic myelopathy. Seven patients had moved from the district and could not be traced. Of the remaining 6 patients, 1 could not be traced owing to demolition in the area of the patient's original address and therefore 5 patients were followed up. These 5 patients have been re-examined and radiographs of the cervical spine have been repeated in order to assess the long-term results of Rogers's procedure.

CASE REPORTS

Case 1.—In 1955 a 55-year-old woman fell downstairs and became rapidly quadriplegic. She developed severe flexor spasms within hours of the injury. After 3 weeks it was observed that the degree of quadriplegia and flexor spasm remained constant. The initial radiographs showed only degenerative changes in the cervical column and the same feature was recorded in the films of the lumbar spine. Films at 4 weeks confirmed the earlier radiological appearance and it is noteworthy that at this time apart from a moderate degree of cervical spondylosis seen particularly at C.V. 5/6/7 there were no fractures and no marked displacement of one vertebra on another. At 5 weeks there was no sign of improvement and myelography was then performed from above and below. A break in the myodil column at C.V. 3/4 and to a lesser extent at C.V. 4/5 was observed. Within 2 months of her cervical laminectomy the patient was able to stand unsupported. Examination in 1972 found her to be walking with a normal gait and with minimal sensory loss in the lower limbs. Neck movements were full and normal. The plantar response remained extensor. A hard boggy mass was readily palpated deep to the laminectomy scar. The radiographs showed a cervical spine with normal alinement.

Case 2.—A 47-year-old man presented in 1956 with a history of left lower-limb weakness of gradual onset following a minor colliery accident the year before. Examination demonstrated atrophy of the small muscles of both hands, fasciculation of the forearm extensors, and exaggerated upper-limb reflexes. There was bilateral lower-limb weakness, the left greater than the right, clonus at both knees and ankles, and bilateral extensor plantar responses. Cervical spondylosis was clearly seen on the plain films and myelography demonstrated a partial block to flow at C.V. 4/5 and C.V. 5/6.

Following complete cervical laminectomy 8 months after the original injury the patient made slow but steady improvement and when examined in 1972 no abnormalities, with the exception of slight limitation in neck movements, were noted. There was a slight fullness deep to the scar. Radiographs showed normal alinement (*Fig.* 1). The patient has continued to work since 1957 and is in full employment.

Case 3.—A 40-year-old woman was admitted in 1956 following a fall downstairs and was noted on admission to have a marked sensory loss below C.V. 5. She became quadriplegic over a period of 3 weeks and a full picture of compressive cervical myelopathy was recorded. At this stage plans were being made for her transfer to a long-stay rehabilitation unit but in view of the success with *Case* 2 further investigations were considered. Eight weeks after the original injury her clinical picture showed no improvement and myelography from above and below demonstrated a block at C.V. 5.

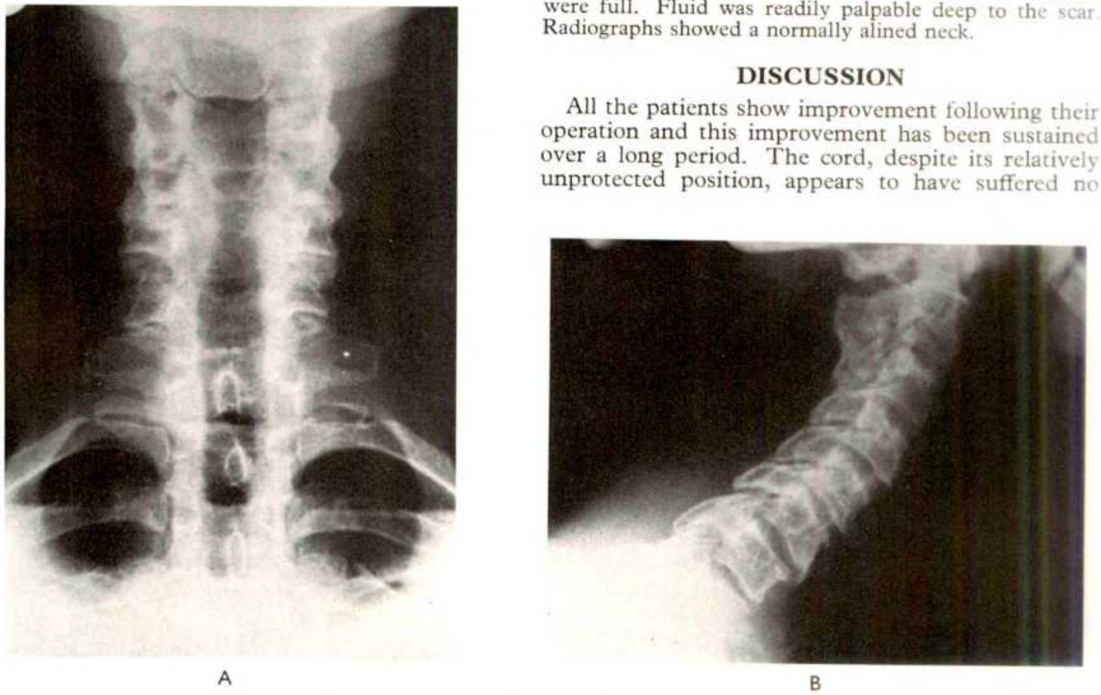

FIG. 1.—*Case* 2. Two views of the cervical spine 14 years after cervical laminectomy.

Following operation the patient made a fair recovery and in 1972 she was able to walk unsupported but with an obvious spastic gait. All neck movements were limited to about half the normal range and there was a fluid collection, presumed to be cerebrospinal fluid, deep to the scar. Radiographs showed no evidence of any abnormality other than marked osteophytosis and the absence of laminae and spines of all the cervical vertebrae.

Case 4.—A 38-year-old man developed numbness and weakness in the left index finger and thumb 3 weeks after a fall at work in 1954. Later, all the digits of both hands became similarly affected. Three months after the original fall he presented with these symptoms in addition to hesitancy of micturition and a dragging left foot. A mild degree of spondylosis was seen on the plain films and the myelogram showed a narrow canal at C.V. 4/5 level.

Following operation the patient had no further urinary difficulty and was back at work within 3 months. He remains in work in 1972 and has no complaints other than clumsiness of fine hand movements. He has full neck movements and the scar is normal. Radiographs show normal alinement.

Case 5.—A 50-year-old man was admitted to hospital in 1960 with a 3-year history of a 'dead' sensation in the hands and dragging of the right foot. Bilateral, generalized upper-limb paraesthesia and flexor fasciculation were present and he was unable to perform fine manual tasks. Despite his complaint no lower-limb weakness was demonstrated, although his reflex responses were exaggerated and he had a bilateral extensor plantar response. Plain films showed degenerative changes throughout the whole spine and there was persistent hold-up of the myodil column at the body of C.V. 5.

Following operation the patient regained a normal gait and power returned to the hands. In 1972 he still had some difficulty with fine movements of the hands, although handwriting comparisons showed there to be a marked improvement from the 1960 picture. Neck movements were full. Fluid was readily palpable deep to the scar. Radiographs showed a normally alined neck.

DISCUSSION

All the patients show improvement following their operation and this improvement has been sustained over a long period. The cord, despite its relatively unprotected position, appears to have suffered no damage in any case. All the spines remain fully mobile with the exception of *Case* 3, which had marked osteophytosis on the 1972 radiographs.

Since the cord and its blood-supply are affected by minor contusions from the prolapsed disk or osteophytic bars protruding into the canal during neck movements, repeated minor injury may be important in the development of cervical myelopathy (O'Connell, 1956). This, together with the established fixation of the cord by the dentate ligaments (Bedford, Bosanquet, and Russell, 1952), justifies the wide exposure and freeing of the cord. But does the threat to neck stability justify such an exposure? The stability of the cervical spine depends on the intervertebral joints, the laminae, spinous processes, ligamentum flavum, interlamina ligaments, and paraspinal muscles and ligaments. Scoliosis and kyphosis have been described following multiple laminectomies in the lumbar and thoracic spine in children (Tachdjian and Mason, 1965), and following cervical laminectomy in 3 children (Cattell and Clark, 1967). Adolescent kyphosis and anterior subluxation has also been described (Bette and Englehardt, 1955). In the adult no such postoperative deformities have been recorded, and Rogers's early confidence in his operation appears to be well justified by the long-term follow-up presented here. During growth structures other than intervertebral joints may be primarily responsible for spinal stability but at maturity the major stabilizing factors may well be the joints themselves, leaving other structures in a position of secondary importance. If the laminae and spinous processes become redundant structural factors, then their removal should produce no defect in stability and movement. This is, in fact, the case.

It is suggested that Rogers's operation, which by comparison with other surgical procedures popularly adopted in the treatment of cervical spondylotic myelopathy is relatively simple, has particular merit not only on the grounds of technique but also in the lack of long-term complications.

BASAL OSTEOTOMY OF THE FIRST METACARPAL IN THE TREATMENT OF ARTHRITIS OF THE CARPOMETACARPAL JOINT OF THE THUMB

BY J. N. WILSON

INSTITUTE OF ORTHOPAEDICS, LONDON

SUMMARY

This is a preliminary report of 8 cases of osteo-arthritis of the carpometacarpal joint of the thumb treated by a basal abduction osteotomy of the first metacarpal.

Follow-up from 6 months to 9 years has shown a relief of pain and an increased function of the hand.

Although the osteotomy has been designed to correct the adduction deformity of the first metacarpal, in 2 cases this correction was not achieved and it is possible that a transverse osteotomy might be just as effective.

OSTEOTOMY has been advised in the treatment of osteo-arthritis of a number of joints. It has been shown to be successful in the relief of pain in osteo-arthritis of the hip (McMurray, 1935; Osborne and Fahrni, 1950; Harris and Kirwan, 1964), and more recently good results have been reported in the use of osteotomy for the treatment of arthritis of the knee (Benjamin, 1969; Jackson, Waugh, and Green, 1969). Pain relief in these cases has often occurred without any other functional improvement and without any regression of the disease process. Osteo-arthritis of the carpometacarpal joint of the thumb is not only painful but is very often associated with an adduction deformity of the first metacarpal—a deformity which can be worsened by the operation of excision of the trapezium or base of the metacarpal. Fusion of the joint, although it corrects the adduction deformity and relieves pain, is sometimes difficult to achieve. It was because of the disadvantages of the standard methods of treatment that a basal osteotomy of the first metacarpal was first carried out 9 years ago. Only severe cases which have not responded to conservative measures have been submitted to surgery. In the author's experience the indication for operation in this condition is relatively infrequent and a large personal series of cases cannot be expected. This paper is therefore a preliminary communication and describes the results of 8 cases which have been followed up for periods varying from 6 months to 9 years.

OPERATION

Osteo-arthritis of the first carpometacarpal joint is nearly always associated with radial subluxation of the base of the metacarpal and subsequent adduction deformity of the shaft of the bone (*Fig.* 1). The aim of the operation is to carry out an abduction osteotomy at the proximal end of the first metacarpal by removing a wedge of bone based radially and closing the defect by abducting the distal fragment. The operation is performed through a 4-cm. incision sited over the proximal half of the metacarpal and in line with the shaft (*Fig.* 2). The extensor tendon of the thumb is retracted to one side and the proximal third of the metacarpal is exposed subperiosteally (*Fig.* 3). The site of the osteotomy, which should be about 1 cm. distal to the carpometacarpal joint, is marked with an osteotome; the size of the wedge necessary to produce an abduction of the metacarpal shaft of 20–30° is approximately 5 mm. at its base. Before bone is removed the wire for fixing the osteotomy must be inserted (*Fig.* 4). Transverse holes are drilled through the proximal and distal fragments about 6 mm. from the base section and 26-gauge wire is threaded into position. The wedge of bone is removed piecemeal using an osteotome and small bone cutters and the cortex on the far side is weakened by two drill holes. The empty wedge left in the bone can then be closed by fracturing the osteotomy and tightening the ends of the wire which are twisted together to maintain the position of the bone (*Fig.* 5). A forearm plaster is applied with the thumb in wide abduction and this position is maintained for 6 weeks (*Fig.* 6).

CLINICAL MATERIAL

The patients under review consisted of 7 women and 1 man. The youngest patient was 54 at the time of operation and the oldest 67. There were no true rheumatoid cases, but in 1 case the E.S.R. was elevated to 24 mm. per hour.

RESULTS

All the patients have been completely relieved of pain and are entirely satisfied with the result of the operation. Powerful grasp action has been restored

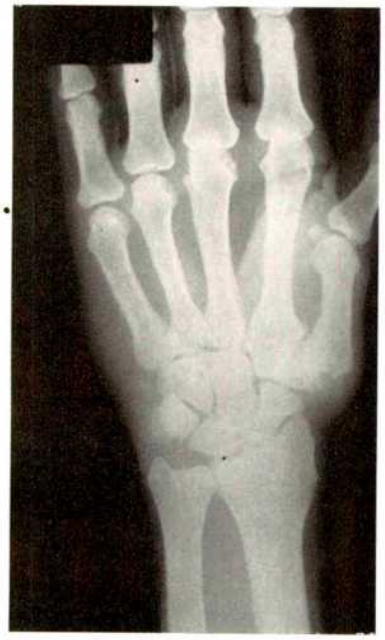

FIG. 1.—Adduction deformity of the first metacarpal typical of osteo-arthritis of the carpometacarpal joint of the thumb.

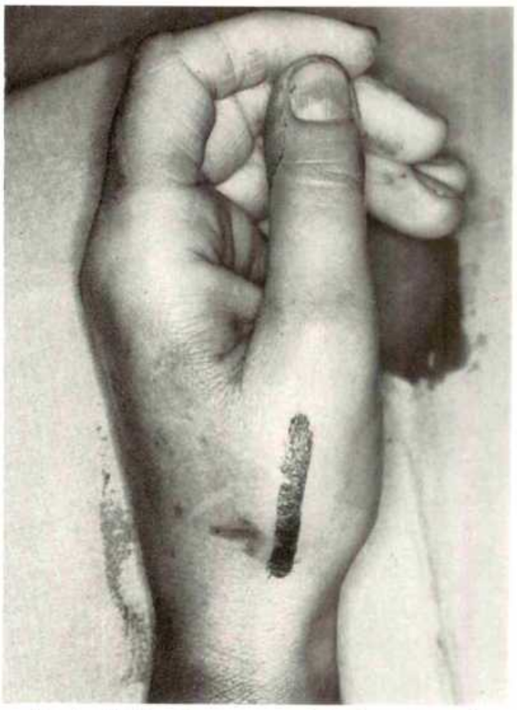

FIG. 2.—Incision for osteotomy of the first metacarpal.

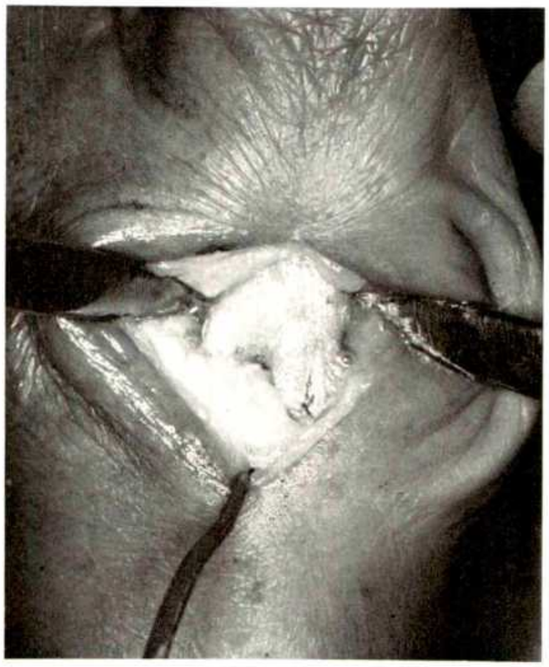

FIG. 3.—Subperiosteal exposure of the lower third of the first metacarpal.

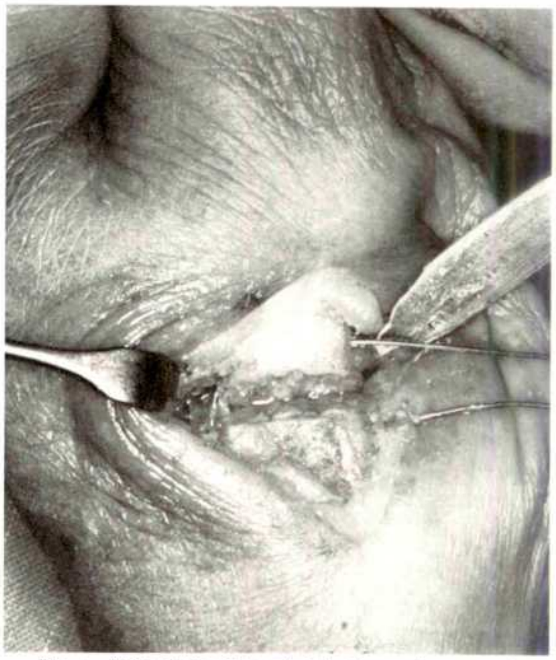

FIG. 4.—Wires in position and abduction wedge removed.

and the improved spread of the hand allows the patients to grip large objects without difficulty (*Fig.* 7). In 2 cases the osteotomy did not correct the adduction deformity of the metacarpal, but despite this there was a complete resolution of symptoms and the thumb-to-finger grasp for large objects was regained by hyper-extension at the metacarpophalangeal joint. There has been no evidence

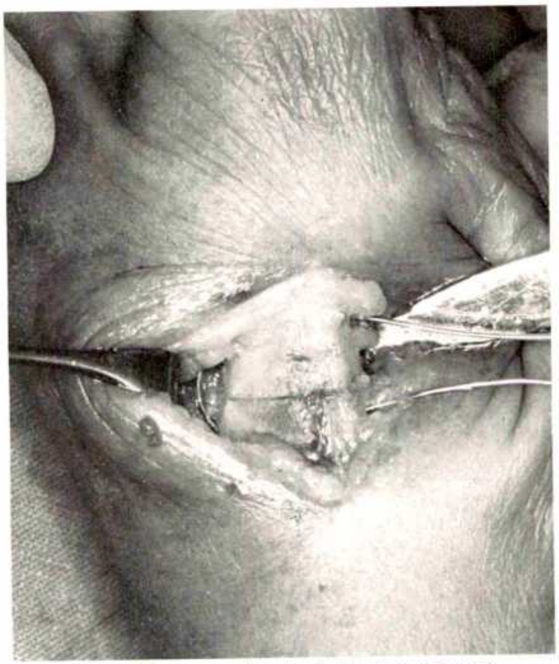

FIG. 5.—Osteotomy closed and wire loop tightened.

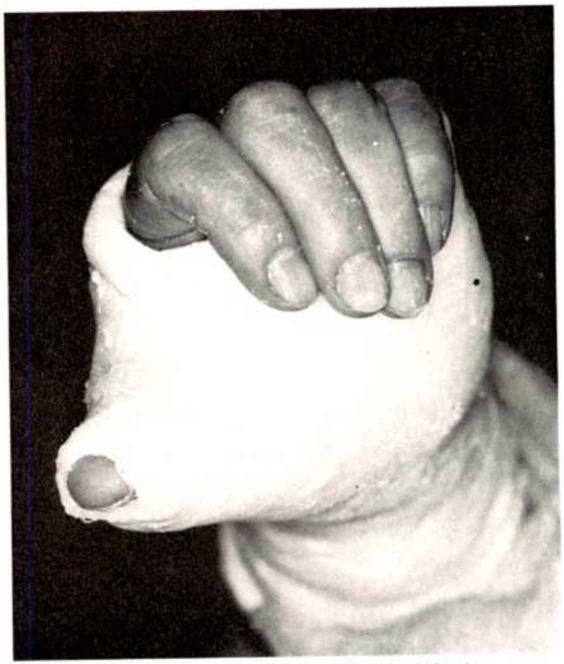

FIG. 6.—Plaster immobilization in wide abduction.

radiologically of further deterioration in the joint after osteotomy, but no improvement in joint appearance has been demonstrated. One patient with bilateral disease had the opposite side treated by excision of the base of the metacarpal, but although this resulted in a painless thumb the patient much preferred the side on which the osteotomy had been carried out because of the restoration of a powerful thumb grasp.

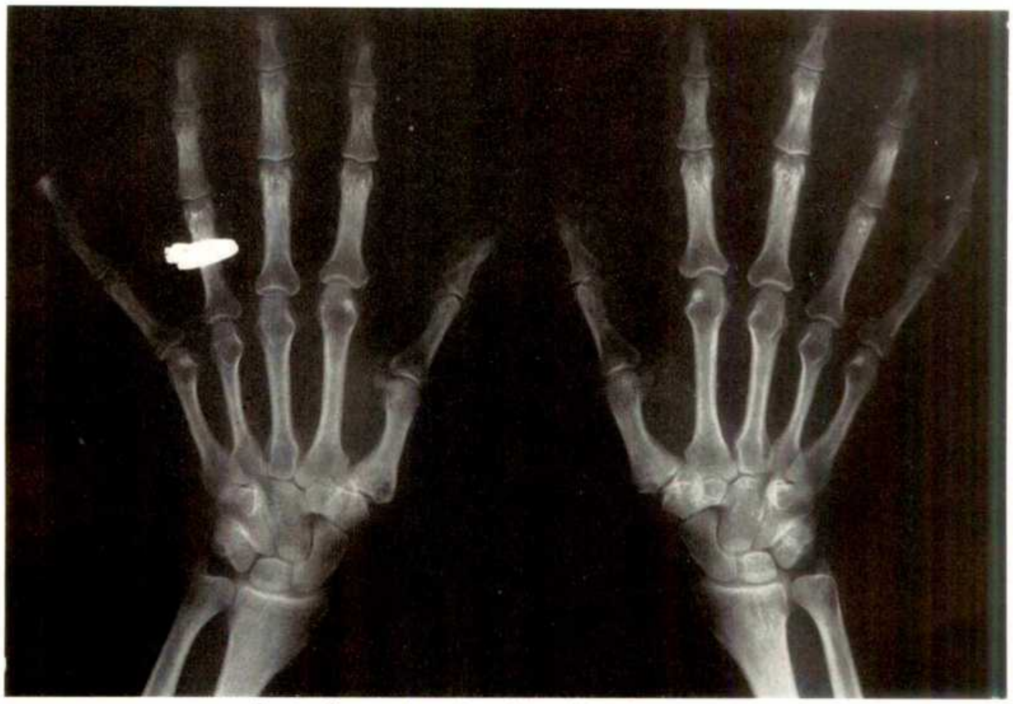

FIG. 8.—Preoperative radiograph in a bilateral case (W. K.).

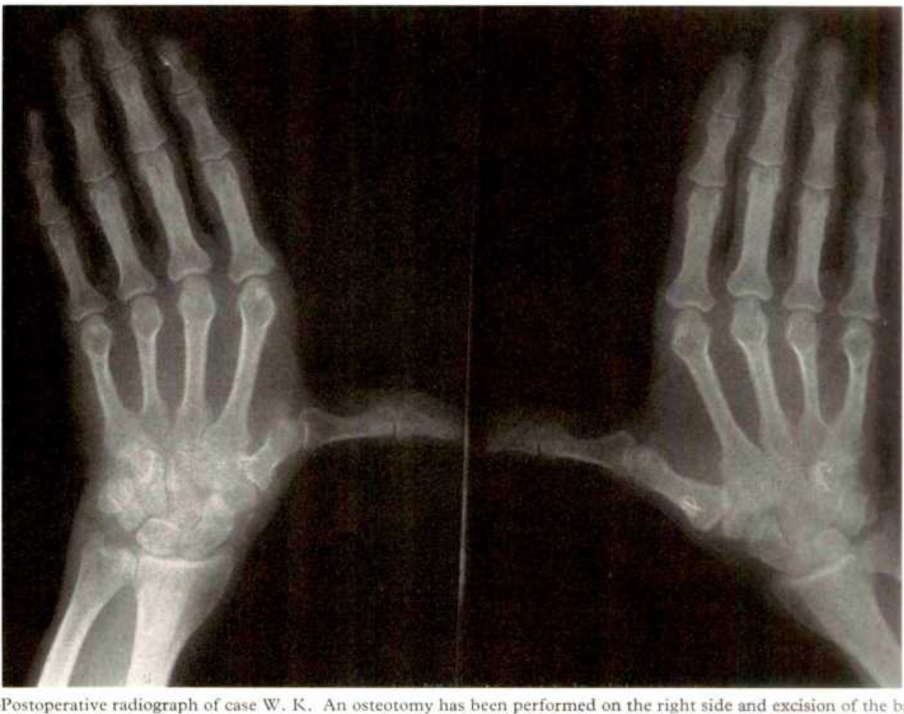

FIG. 9.—Postoperative radiograph of case W. K. An osteotomy has been performed on the right side and excision of the base of the metacarpal on the left side.

CASE REPORT

W. K., a 59-year-old woman, had a history of carpometacarpal arthritis of both thumbs for 10 years (*Fig.* 8). In 1962 an excision of the base of the left first metacarpal was carried out, but although pain was relieved the patient developed increased adduction deformity and did not regain a satisfactory grasp. In 1964 she had a 20° abduction osteotomy through the base of the metacarpal on the right side. At the time of review 9 years later the patient was free of pain on both sides but the adduction deformity of the first metacarpal on the left side had increased, whereas on the side of the osteotomy a normal spread of the thumb had been regained (*Figs.* 9 and 10). The difference in grasp power of the two thumbs is illustrated in *Fig.* 11.

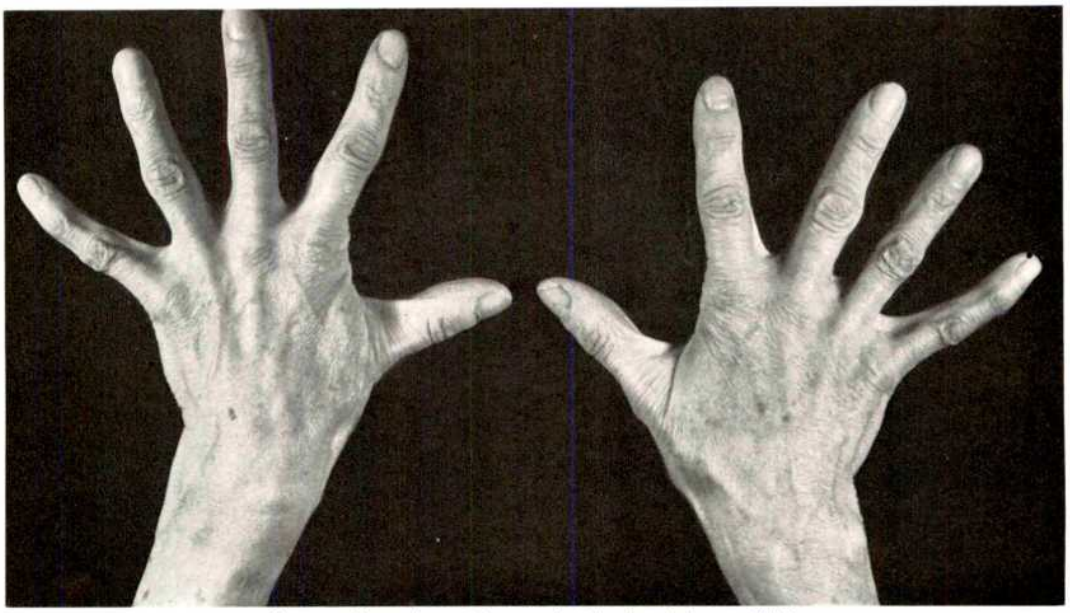

FIG. 10.—Comparison of the spread of the thumbs in case W. K.

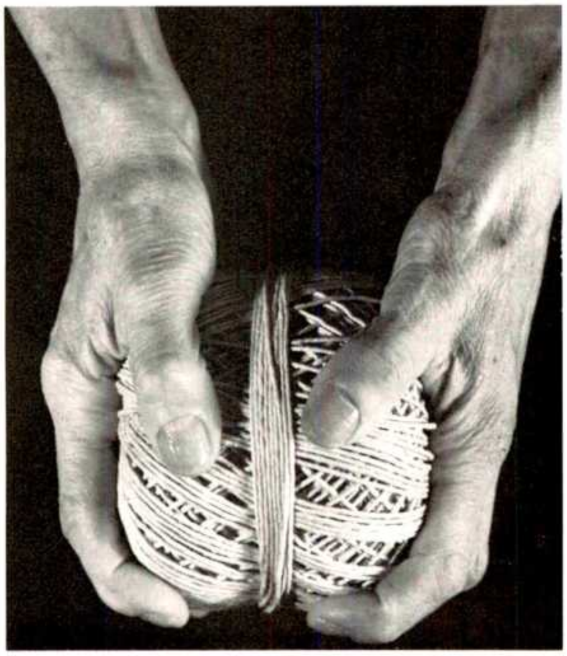

FIG. 11.—Comparison of the grasp in case W. K.

COMPLICATIONS

In no case has there been any significant complication. All the osteotomies have been radiologically united within 3 months, and although the wire fixation has broken in 1 case this has not caused any disability. In 1 patient there was a minor loss of sensation at the tip of the thumb, presumably owing to involvement of a branch of the digital nerve, but this has proved to be no disability.

Acknowledgements.—I am grateful to Mr. R. J. Whitley of the Photographic Department, Institute of Orthopaedics, for reproduction of the photographs and radiographs, and to my secretary, Miss Doreen Fox, for preparation of the manuscript.

SUBCAPITAL FRACTURES OF THE NECK OF THE FEMUR TREATED BY DOUBLE-DIVERGENT FIXATION

By W. M. McQUILLAN, P. J. ABERNETHY, and J. G. GUY

ROYAL INFIRMARY, EDINBURGH

SUMMARY

A method of fixation of femoral neck fractures which involves double-divergent fixation using two Watson-Jones nails is described. The method has been compared against nail and autogenous fibular graft fixation and gave results which were better. The method has also been compared against single-nail fixation and has given much better results. There seems to be little place for single-nail fixation of displaced femoral neck fractures.

A clinical series of 90 cases of displaced fractures treated by double-divergent fixation is presented. Failure of fixation occurred in 12 cases (13·3 per cent).

The technique of double-divergent fixation prevents femoral neck collapse or resorption.

THE intracapsular fracture of the femoral neck has often been referred to in the past as the 'unsolved fracture' (Dickson, 1953), but nowadays there are some grounds for a more optimistic view.

There is considerable uncertainty about the ideal treatment, but the incidence of this fracture is high and some scheme of management is necessary. Over the years a vast literature has accumulated. Internal fixation by a trifin nail was introduced in 1931 (Smith-Petersen, Cave, and Van Garder, 1931), since when various series and many modifications have been described: nail and autogenous bone-graft, trans-articular nailing, the use of compression screws, nail plates, sliding nails and plates, multiple pins, cross-screws, etc. (Moore, 1937; Brittain, 1942; Patrick, 1949; Jewett, Albee, Powers, and Stanford, 1952; Pugh, 1955; Schumpelick, 1955; Charnley, Blockey, and Purser, 1957; Massie, 1958; Deyerle, 1959; Hargadon and Pearson, 1963; Brown and Abrami, 1964; Burton, 1964; Garden, 1961a, b; Jarry, 1964; Smyth, Ellis, Manifold, and Dewey, 1964; Metz, Sellers, Feagin, Levine, Onkey, Dwyer, and Eberhard, 1970). The variety in style and complexity of the devices is clear evidence of the lack of a uniformly satisfactory method. Because of the dissatisfaction which surrounds internal fixation it is not surprising that immediate prosthetic replacement of the head of the femur has become an alternative method of management, but this technique has a significant incidence of complications and the patients are not all free from symptoms at a later stage (Hinchey and Day, 1964; Thomson, 1968; Rush, 1971).

Reports of the success of early weight-bearing after internal fixation (Abrami and Stevens, 1964; Gibson, 1964) have led to a renewal of interest in internal fixation as a primary treatment. To allow early weight-bearing the fixation device should be mechanically capable of sustaining the loads imposed (Frankel, 1959). This leads to increasing technical complexity, considerably increased operation time, or liability to technical failure.

This paper describes a method of fixation which has been used in Edinburgh since 1964 (McQuillan, 1966, 1968). The method uses two standard Watson-Jones nails. A pilot study of 12 cases was carried out and the results were satisfactory. Further work was done by random testing of the method of double-divergent fixation by two Watson-Jones nails against two other methods.

CASE MATERIAL

The method has been used in the treatment of patients with displaced femoral neck fractures. Garden's classification has been used in the assessment of the degree of displacement (Garden, 1964). Fractures with displacement of Garden's grades 1 and 2 have been treated where no difficulty has been encountered, the results being satisfactory. Other methods are equally satisfactory in these types of fracture (Fielding, Wilson, and Zekel, 1962; Bentley, 1968).

The cases to be reported here are all displaced fractures of Garden's grade 3 or 4. The patients were aged 45 years or over with displaced fractures of the femoral neck, either subcapital or transcervical (Watson-Jones, 1955; Klenerman and Marcuson, 1970), who were able to walk before their fracture, which was not itself pathological other than as a result of osteoporosis.

METHOD OF REDUCTION AND DOUBLE-DIVERGENT FIXATION

In the treatment of displaced fractures a satisfactory reduction is important (Watson-Jones, 1955; Garden, 1964).

Vigorous or formal manipulation of the fracture has not been used. It is believed to be unnecessary and possibly harmful. The method of reduction has been to apply gentle traction with the patient under general anaesthesia on a Charnley table, the leg being held in a neutral position in the first instance. Radiographs are then taken. In about 60 per cent of cases the fracture is seen to be in an anatomical position provided that the leg is immobilized in *neutral* and *not* in abduction and internal rotation. In 30 per cent of cases adjustment of the position is required—usually some increase in internal rotation. In the remaining 10 per cent of cases these measures may not be sufficient to produce an acceptable reduction and the procedure may need to be repeated. In a tiny percentage an open reduction may be required when failure to achieve reduction by simple measures is seen to be due to local mechanical problems, e.g., a spike of bone piercing the capsule.

An anatomical or near anatomical reduction is necessary before proceeding further. The operative steps to be undertaken must be carried out in a precise and regulated way or problems will ensue.

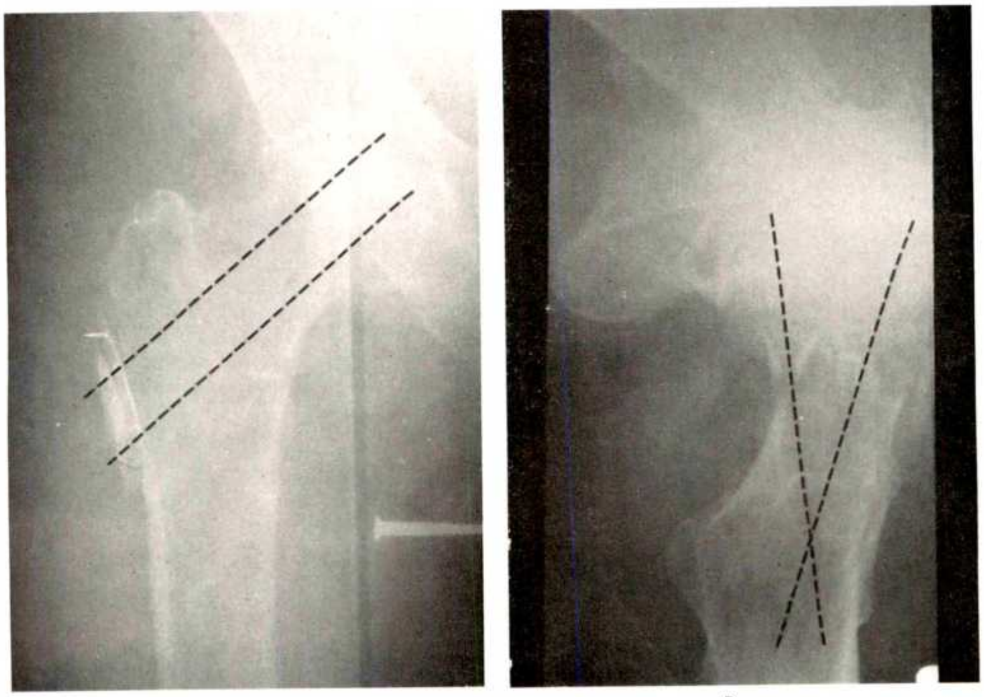

FIG. 1.—Radiographs illustrating the technique of insertion of guide-wires. The fracture has been reduced as described in the text. Lines are drawn on the post-reduction radiographs in the positions in which it is desired to place the nails. On the anteroposterior view (A) the distances from the vastus ridge can be estimated together with the angle to the shaft. (The angles are not changed materially by X-ray distortion and the distances are increased.) On the lateral view (B) the angles to the horizontal can be estimated. The upper wire normally passes forwards so that the drill hole preparatory to insertion of the wire usually lies behind the midpoint of the shaft. The lower wire will pass backwards into the head and the drill hole thus is usually forward of the midline of the shaft.

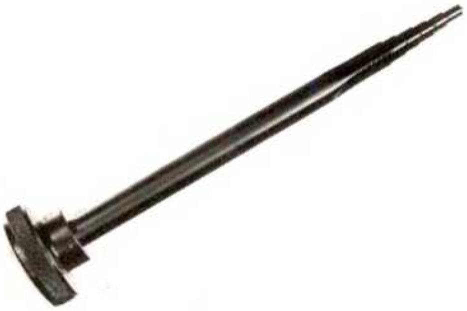

FIG. 2.—The Ritchey starter provides a clean trifin cut around the guide-wire. A plastic mallet is a useful addition. When used properly the starter locks in the guide-wire and makes an ideal starting hole in the shaft without fragmentation. This is the only 'new' instrument necessary.

Operative Details.—The lateral side of the thigh is exposed through a curved incision. This incision reduces the need for forceful retraction and gives better exposure than a straight incision. The vastus lateralis is reflected from its ridge, exposing the lateral side of the femur. The vastus ridge is used as a landmark. On the post-reduction films guide-lines can be drawn as shown in *Fig.* 1 from which it is possible to estimate the angles and the directions of the guide-wires to be inserted through preparatory drill holes. Two guide-wires only are used. Protractors and a ruler corrected for the radiographic magnification are helpful, but with increasing experience these aids do not prove necessary.

When the desired position has been achieved the guide-wires are driven across the head of the femur into the acetabulum to prevent tilting of the head as the nails are inserted. The Ritchey starter (*Fig.* 2) provides a clean trifin cut and does not fragment the cortex, a problem which can result from the use of some other instruments. The nails are introduced one at a time, the nails being driven alternately. The guide-wires are withdrawn and the position of the nails is checked by radiographs. Traction should be released at this stage and an additional tap given to each nail. Formal impaction is not carried out as it will not achieve any advantage with the desired nail position.

Preservation of the integrity of the lateral cortex is important, and allowed for by the use of the Ritchey starter.

Position of the Nails.—The optimum position of the nails is as shown in *Fig.* 3. In the anteroposterior view a parallel or minimally divergent position of the nails is chosen, while in the lateral view the upper nail can be seen to pass into the centre or anterior aspect of the head and the lower nail is positioned posteriorly, clear divergence of the nails being obtained. It should be noted that with this type of fixation further impaction is not possible.

It may appear radiologically that a great deal of metal is present. The radiological appearances do not allow for the trifin section of the nails.

The nails will be contained easily within the neck of the femur as illustrated in *Fig.* 4.

POSTOPERATIVE MANAGEMENT

Early weight-bearing is encouraged with whatever assistance (Zimmer aid, crutches, or sticks) is required by the patient for comfort and security. Some patients have walked on the day after operation while others have not until 1 week later but all the patients in the present series have been encouraged towards full weight-bearing as soon as possible.

Routine anticoagulation can give problems in elderly patients (McQuillan, 1964). In this series the measures used to reduce the incidence of thrombo-embolism have been:—

1. *Early operation*: Where possible, surgery has been carried out within a few hours of admission and rarely later than 24 hours after injury.
2. *Speedy operation*: This procedure can be carried out within ¾–1 hour, the time being greatly reduced with experience.
3. *Early mobilization and ambulation.*

These measures appear to have been very satisfactory in the prophylaxis of deep venous thrombosis and pulmonary embolism.

RESULTS

Pilot Study.—The traditional method of treatment of displaced fractures of the femoral neck by a single trifin nail has given results which were less than satisfactory (Welch, 1966). The nail-and-graft procedure as reported by Patrick (1949) was used as an alternative for a time but without a great improvement in the results. The use of the graft raised the question as to whether the fibular graft acted as a bone graft or whether its value was purely mechanical, so that better fixation was achieved than with one nail alone. Clearly one method of determining whether the fibular graft acted as a mechanical aid or whether it acted biologically could be determined by carrying out a comparative study using two mechanical devices without osteogenic properties. A preliminary study was carried out in which 12 patients were treated by double-nail fixation. This showed the technical feasibility of the operation and its relative simplicity as compared with the nail-and-graft operation. The results were entirely satisfactory in that all 12 patients had good results although there were many variables in these cases.

Controlled Surgical Trial.—It seemed important to evaluate double-divergent fixation against the nail-and-graft procedure (*Fig.* 5) by a controlled surgical trial.

Patients (*vide supra*) with displaced fractures of the femoral neck of Garden's grade 3 or 4, the fracture not being pathological, who were otherwise fit for operation and who had walked before the incident, were included in this trial.

A random index was produced prospectively for operation by two nails or nail and graft. As patients were admitted to the unit the index was consulted to determine the procedure to which they should be submitted, i.e., the next one listed. Fifty-four cases were dealt with in this fashion. The results are shown in *Table I*.

Table I.—RESULTS OF A CONTROLLED TRIAL OF DOUBLE-DIVERGENT FIXATION COMPARED WITH NAIL AND GRAFT IN 54 PATIENTS

	NAIL AND GRAFT	DOUBLE-DIVERGENT FIXATION
Total number of cases	27	27
United	10	17
Held. ? union	3	2
Failed	6*	1
Total number of deaths	8	7
Up to 1 mth.	2	1
Fracture failure	1	0
1 mth.–2 yr.	6	6
Fracture failure	1	1
Total number of failures	8	2
Late complications, avascular necrosis	3	2

* Infection occurred in 1 case.

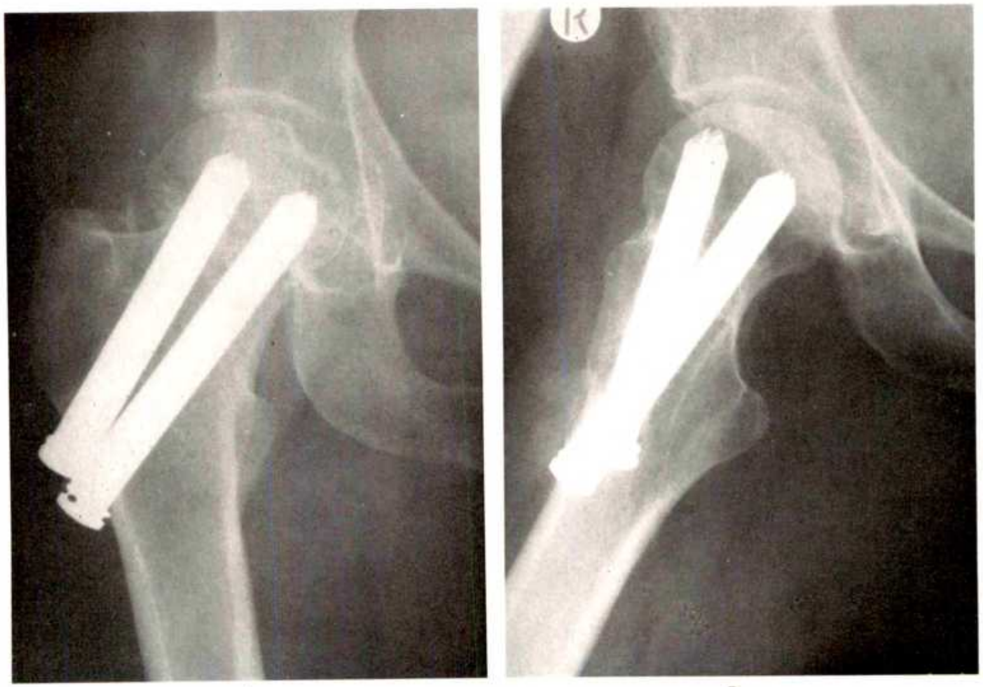
It seems clear from this evidence that two-nail fixation has advantages over the nail-and-graft procedure. It commends itself by virtue of the results of fixation and, just as importantly, because it is technically easier, it does not involve a second operative procedure on the same patient for removal of the graft, and it produces a satisfactory clinical result. The method allowed early walking with pain relief in the vast majority of patients.

Second Clinical Trial.—Although the published results of single-nail fixation are much poorer than the results obtained by double-divergent fixation there is no firm evidence to justify the conclusion that double-divergent fixation is superior to single-nail fixation if the latter procedure is carefully carried out. It was therefore decided to conduct a trial of two-nail against single-nail fixation in which an experienced surgeon would carry out all the operations.

A second clinical trial was therefore carried out on patients with displaced fractures, this time the random index selecting patients for single- or two-nail fixation. A further 50 hips in 49 patients were treated during the process of this controlled trial. One patient provided the ideal controlled situation (*Fig.* 6).

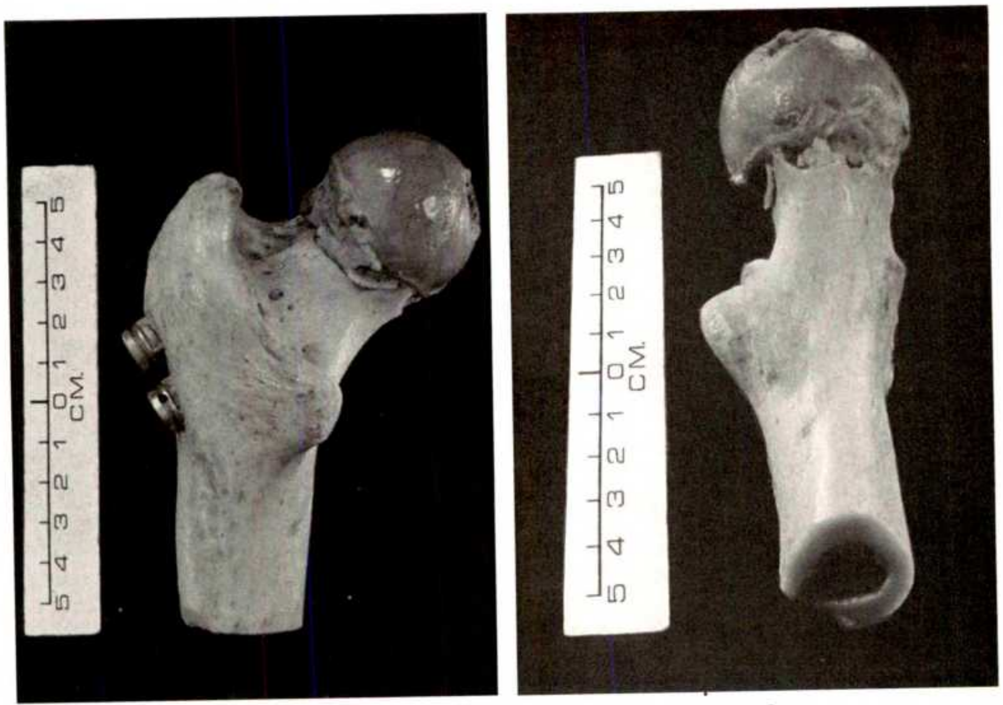
In this trial full consideration was given to achieving the best reduction and fixation by each method. The procedures were carried out by the same surgeon. The results are as shown in *Table II*.

The failure rate of single fixation in displaced fractures was almost 50 per cent, a figure similar to that found in a much larger series (Welch, 1966) and unacceptably high for clinical practice.



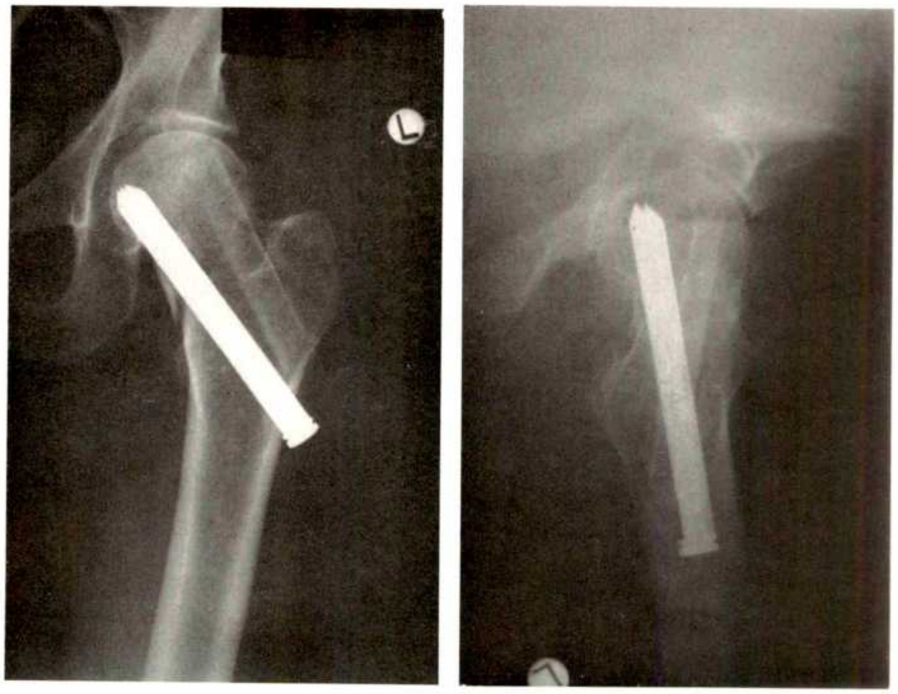
A B

FIG. 3.—The nails should be parallel or slightly divergent in the anteroposterior view (A). It is easier to converge the nails but this is less satisfactory. In the lateral view (B) the nails can be seen to diverge, the lower nail strutting across the commonly found posterior comminution while the anterior nail passes forwards into the head.



A B

FIG. 4.—These photographs are of a specimen removed at autopsy from a female patient who died 2 weeks after operation. This femoral neck is small but the nails are easily contained. (The fixation obtained has defied many attempts to disrupt it by manual force.)



A B

FIG. 5.—The position of fixation in the nail-and-graft procedure. The positions are similar to those already described in the technique of double-divergent fixation, with the graft taking the upper and anterior position.

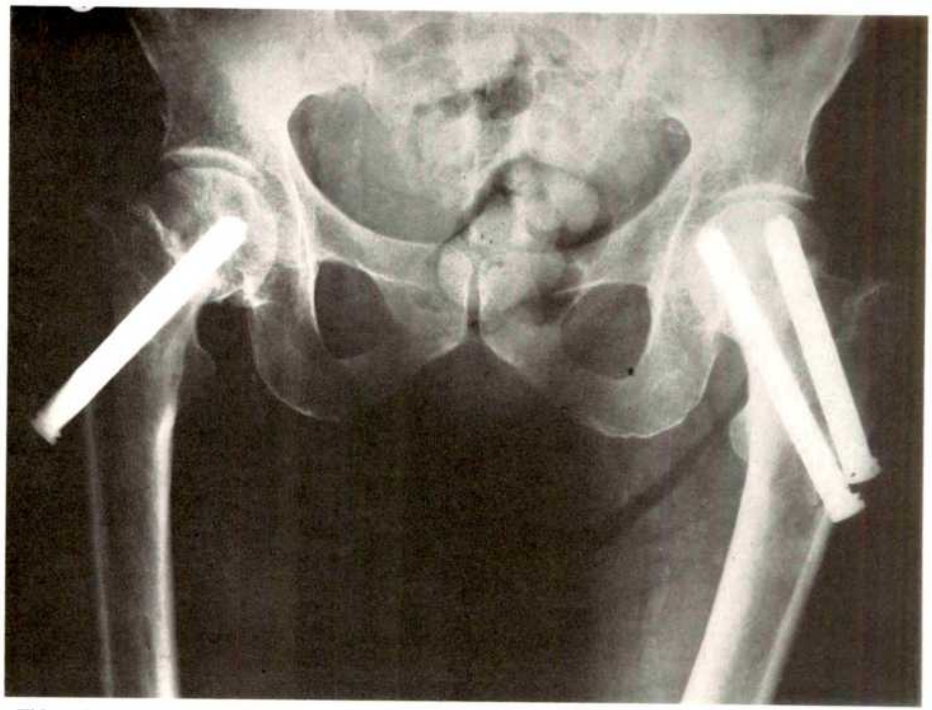


FIG. 6.—This patient sustained two fractures during the time of the trial. The left hip was treated initially by two-nail fixation. Four months later she was readmitted having fractured the right hip and had a single nail inserted (according to the random index). At 10 weeks there is failure of fixation and non-union of the right hip.

At this stage the second clinical trial was abandoned as it seemed clear that no further purpose could be served in continuing it, the results showing that double-divergent fixation is superior in all aspects to single-nail fixation in patients with displaced femoral neck fractures.

Further Clinical Experience.—It was decided to increase the experience of double-divergent fixation and in particular to extend its use so that the operation could be evaluated when performed by a less experienced staff. A further 90 operations have been carried out of which the majority have been done by registrars in training. (It is probable that in routine clinical practice the majority of operations for elderly patients with femoral neck fractures are done by junior staff.)

Although mechanically simple, the method will give rise to technical difficulties unless it is carried out properly and precisely. After adequate experience of simple hip operations, registrars have been given careful instruction and supervision in the method of double-divergent fixation before operating without immediate supervision.

These criteria having been met, the majority of the operative procedures on the 90 patients in this group have been carried out by a considerable number of registrars and senior registrars of varying grades of experience.

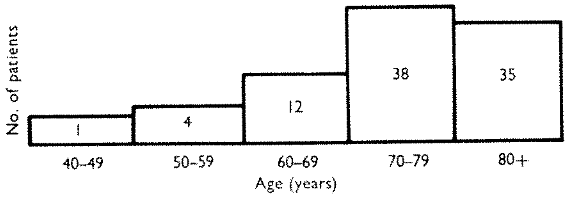

FIG. 7.—Age distribution of 90 patients (average age, 79·8 years) who were operated on by junior hospital staff.

Table II.—RESULTS OF A CONTROLLED TRIAL OF DOUBLE-DIVERGENT FIXATION COMPARED WITH SINGLE-NAIL FIXATION IN 50 PATIENTS

Table VI.—ANALYSIS OF FAILURE OF FIXATION IN 90 PATIENTS AFTER DOUBLE-DIVERGENT FIXATION

1. Failure *v.* delay in surgery
    5 under 24 hours
    7 over 24 hours
2. Failure *v.* type of fracture
    8 type 4
    4 type 3
3. Failure *v.* reduction/fixation
    6 good reductions and good nails (1 syphilis)
    1 good reduction and poor nails
    3 fair reductions and poor nails
    2 fair reductions and accurate nails
4. Failure *v.* age
    3, 60–70 years age-group
    9, over 70 years
5. Associated pathology
    3 associated bone pathology
    2 rheumatoid arthritis
    1 syphilis
    All failed

The assessment of the mortality-rate in hip fractures is a controversial problem and many different rates are described which are meaningless unless specified precisely. In this series (*Table IV*) the mortality-rate is given at 1 week and at 1 year and the arbitrary figure of the in-patient mortality-rate is included. The in-patient mortality-rate of 10 per cent compares favourably with reported results using other methods.

Some controversy exists as to whether fractures which have failed to unite have failed because of avascular necrosis of the femoral head or because of failure of fixation. The results for avascular necrosis (*Table V*) include 4 cases where union did not occur. These are also included in the group of failures where histological analysis of the head removed at subsequent reoperation showed total necrosis of the femoral head. The incidence of avascular necrosis in the fractures which united was 9 cases, of which 6 developed segmental necrosis and 3 had late total head necrosis after fracture union. A total figure for avascular necrosis in patients of this age-group is difficult to obtain, but it should be remembered that segmental necrosis in elderly patients is not a major complication and may not require further surgical treatment.

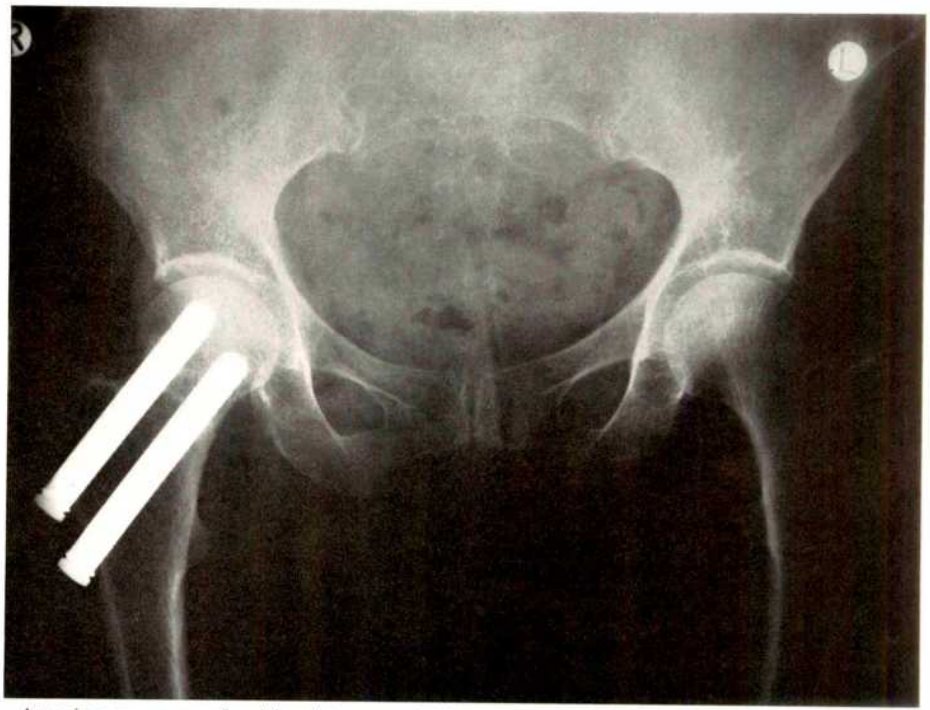

FIG. 9.—A precise measurement of neck length is extremely difficult to obtain. This radiograph illustrates the type of case classified as showing no neck resorption. There is union, maintenance af Shenton's line, and a normal calcar femorale, and the lesser trochanter occupies a normal position as compared with the uninjured side.

Table VI details the cases where there was failure of fixation. No firm conclusions can be drawn but it is of interest that in 6 of the 12 failures there were 3 cases with associated bone pathology, 2 cases of rheumatoid arthritis, and 1 syphilitic case. There were 6 failures amongst the patients who were classified as having good reductions with good fixation, one of these being the syphilitic case already referred to.

DISCUSSION

Evidence from the literature supports strongly the concept of multiple fixation of femoral neck fractures rather than single fixation (Moore, 1937; Deyerle, 1959; Schumpelick, 1955; Strange, 1971). The results of our trial of double fixation compared with single fixation show that the technique of double-divergent fixation is superior. The percentage success in our larger series of 'routine' cases reflects firmly the advantage of two-nail fixation over the traditional single-nail technique.

The study of two-nail fixation against nail and autogenous graft is also in favour of the two-nail method. This does not invalidate the nail-and-graft method *per se* in certain cases. The case material of the present series was largely confined to elderly females in whom a prepared fibular graft is neither ideal as a bone-graft nor does it provide rigid mechanical fixation. The method may have a place in younger patients or where delay has occurred before hospitalization, but we believe that in elderly patients the nail-and-graft method has no advantages over two-nail fixation.

Table VII.—INCIDENCE OF NECK RESORPTION IN 61 PATIENTS WITH A UNITED FRACTURE AFTER DOUBLE-DIVERGENT FIXATION

Neck Resorption	*No. of Cases*
None	42
Avascular necrosis	4
Minimal	10
Avascular necrosis	1
Marked	9
Avascular necrosis	4

There are some additional findings of great interest in this series. It was noted clinically that neck resorption was not an inevitable accompaniment of healing, although it is often alleged that this is so and indeed sliding devices are designed in the belief that some movement is necessary to maintain firm contact at the fracture site (Brown and Abrami, 1964).

Table VII gives an analysis of our cases where union occurred and shows clearly that neck resorption is not inevitable (*Fig.* 9); indeed, it occurred only in a minority of these cases. It is tempting to infer that neck resorption is a reflection of inadequate fixation. If this were so, then clearly sliding devices are constructed on a false premiss and are designed to deal with pathology which is secondary to the mechanical inadequacy of the device.

This paper reports a clinical study and detailed mechanical studies are without its compass. An assessment by the Department of Mechanical Engineering, University of Edinburgh, suggests that double-divergent fixation is mechanically sound (Barr, 1971) and our results would support this view.

The results of any series are always open to discussion as to what constitutes mortality-rate, union rate, etc., and whether cases which are ultimately fatal should be excluded from the results. In this series a full analysis of the results in all the cases has been given without exclusions. The figures of the mortality-rate, union rate, and late complications justify the continued use of the technique and support the firm clinical impression that the method is sound and eminently practical.

Acknowledgements.—We wish to thank the consultants at the Royal Infirmary of Edinburgh who have kindly referred cases for treatment, successive senior registrars and registrars who have operated on many of the cases, successive house surgeons who have documented the cases and contributed to their management, and Mrs. E. Wilson for secretarial help.

CARCINOMA OF THE DUODENUM: COMPARISON OF SURGERY, RADIOTHERAPY, AND CHEMOTHERAPY

BY SAMUEL SAKKER* AND C. C. WARE

SOUTHEND GENERAL HOSPITAL

SUMMARY

Three cases of infra-ampullary carcinoma of the duodenum are presented, and in each case the management was different.

A new method of reimplantation of the common bile-duct and pancreatic duct is described.

One hundred and twenty-six cases from reports in the past decade have been reviewed, and the distribution, sex ratio, clinical features, investigations, management, and prognosis are discussed.

In polyposis investigation of the upper gastrointestinal tract is advised.

The use of radiotherapy and chemotherapy is discussed and advocated.

CARCINOMA of the duodenum is an uncommon condition and most of our knowledge is based on necropsy studies in overseas literature. In the past decade a small number of individual cases and short series have been reported, but in most reports the data are meagre and incomplete.

Increased awareness of the condition, improvement in diagnostic techniques, and a more aggressive surgical approach have combined to change this disease from a post-mortem curiosity to a condition that can be treated with satisfactory results.

Three new cases are presented here, and are discussed with 123 cases reported in the literature in the past 10 years.

CASE REPORTS

Case 1.—V. G., a female aged 51 years, gave a history of anorexia, lassitude, weakness, and weight-loss of 13 kg. over a period of 6 months, followed by severe colicky lower abdominal pain for 1 week. She had vomited twice, bringing up bile, but gave no history of dysphagia, haematemesis, melaena, or jaundice.

She was a known diabetic since 1964 and was controlled with tolbutamide. In 1965 she underwent a laparotomy for acute abdomen and was found to have a papillary cyst adenocarcinoma of her ovary, which was initially treated with salpingo-oophorectomy, followed by total hysterectomy. There was no evidence of recurrence on regular follow-up.

Examination showed the patient to be pale, and her weight was 60·5 kg. There was an epigastric mass approximately 4 cm. in diameter and fixed to the posterior abdominal wall.

Investigations showed the haemoglobin to be 9·6 g. per 100 ml. and there was occult blood in her stools. Barium-meal examination showed the abdominal mass to correspond with a stenotic area in the third part of the duodenum (*Fig.* 1).

A laparotomy was performed in the first week of June, 1971, and the tumour was found to be in the infra-ampullary part of the duodenum. It was adherent to the pancreas, aorta, and left renal vein. It also involved the mesentery of the small intestine and the transverse colon, where some moderately enlarged lymph-nodes were palpable. The liver was free from metastases, and there was no evidence of recurrence of the previous carcinoma of the ovary in the pelvis.

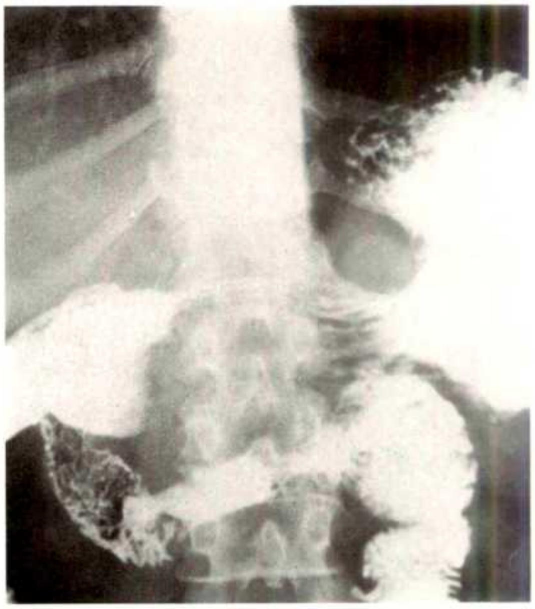

FIG. 1.—*Case* 1. Barium-meal film showing the stenotic tumour and ulcer in the third part of the duodenum.

The tumour mass was dissected from the middle colic vessels and portal vein, and was shaved off the aorta, the left renal vein, and the head of the pancreas. It was necrotic, friable, and microscopically incompletely excised. A segmental resection of the duodenum was carried out with a 1·5-cm. clearance of normal mucosa at the proximal end and an 8-cm. clearance at its distal end. Proximally the duodenum was divided above the ampulla and it was found that a separate common bile-duct and pancreatic duct were coursing for about 1·5 cm. along the posterior wall of the duodenum. These were dissected free and reimplanted through a stab incision in the duodenal wall in order to free about 1 cm. of duodenum for anastomosis (*Fig.* 2). The common bile-duct and the pancreatic duct were re-embedded in the duodenal lumen around a plastic tube splint, and the continuity of the bowel was restored with a conventional two-layer continuous chromic catgut end-to-end anastomosis.

The pathology report confirmed the operative finding of a necrotic friable tumour. A malignant ulcer measuring 7 × 7 cm. completely encircled the lumen of the bowel and extended to 1·5 cm. of the cut edge.

Microscopy showed a well-differentiated adenocarcinoma which appeared to be arising in the mucosa (*Fig.* 3).

Postoperative management was with intravenous fluids, nasogastric suction, and a sliding scale of intramuscular soluble insulin. Progress was uneventful and the patient made a rapid recovery.

---

* Present address: 52 Fourth Avenue, Eastwood 2122, New South Wales, Australia.

In view of this patient's remarkable progress and the knowledge that the resection had not completely removed all the tumour tissue it was decided to give her a course of 5-fluoro-uracil; 500 mg. were given intravenously, nightly, under haematological control for 1 week, then weekly in the out-patients' department for 3 months.

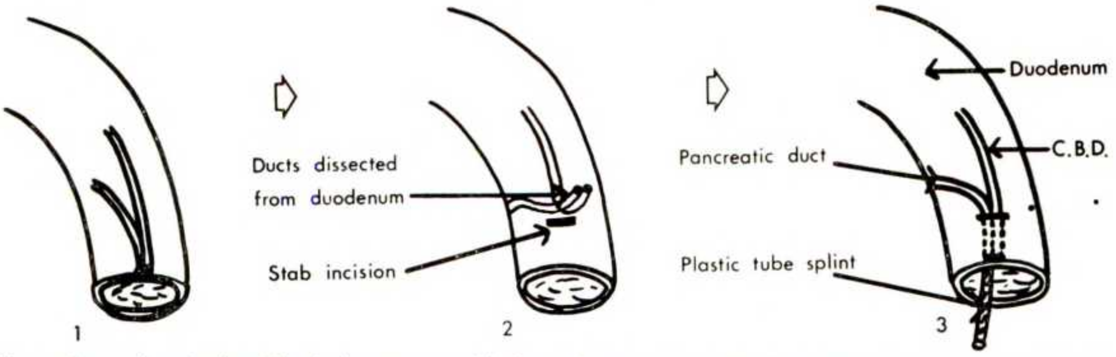

FIG. 2.—*Case* 1. Posterior view of the duodenum, common bile-duct, and pancreatic duct. The ducts were dissected free from the posterior wall of the second part of the duodenum and reimplanted through a stab incision in the duodenal wall around a plastic splint.

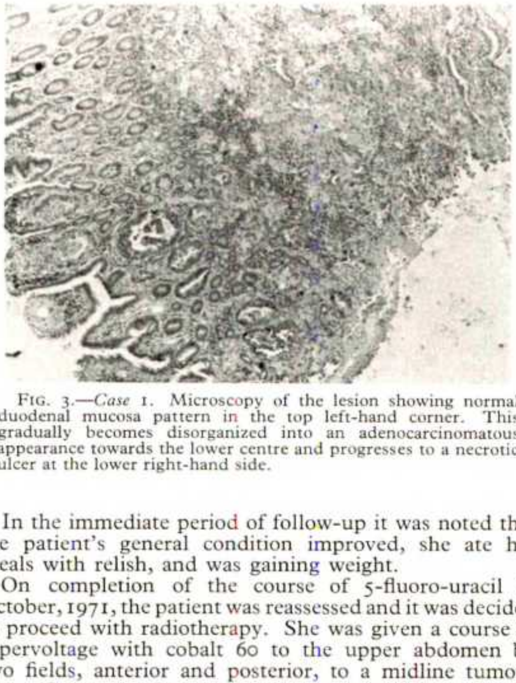

FIG. 3.—*Case* 1. Microscopy of the lesion showing normal duodenal mucosa pattern in the top left-hand corner. This gradually becomes disorganized into an adenocarcinomatous appearance towards the lower centre and progresses to a necrotic ulcer at the lower right-hand side.

In the immediate period of follow-up it was noted that the patient's general condition improved, she ate her meals with relish, and was gaining weight.

On completion of the course of 5-fluoro-uracil in October, 1971, the patient was reassessed and it was decided to proceed with radiotherapy. She was given a course of supervoltage with cobalt 60 to the upper abdomen by two fields, anterior and posterior, to a midline tumour dose of 5000 r with thirty treatments over a period of 43 days.

She progressed well, was asymptomatic, and when last seen, 22 months after her operation, had gained 10 kg. in weight.

Case 2.—R. B., a female aged 74 years, complained of dyspnoea, epigastric pain, and vomiting for 5 months. These symptoms were temporarily relieved by alkalis, but 2 months later were followed by weakness, weight-loss, anorexia, nausea, and continuous vomiting.

Examination showed a thin woman with a vague mass in the left hypochondrium.

Investigations showed her haemoglobin to be 11·7 g. per 100 ml. with a white-cell count of 8000 per mm.^{3} A repeat barium-meal examination showed a stricture at the distal end of the third part of the duodenum (*Fig.* 4).

At operation an encircling tumour causing a complete obstruction was found at the distal end of the third part of the duodenum. It was invading the peritoneum and retroperitoneal structures and was unresectable. A gastro-jejunostomy was performed and the biopsy taken was reported as 'fat infiltrated by columnar cell, mucus-secreting adenocarcinoma of gastro-intestinal origin'.

The patient's postoperative progress was uneventful and she was treated with a course of radiotherapy to a total tumour dose of 5000 r, and chemotherapy with 5-fluoro-uracil intravenously over a period of 3 months was also given. She progressed well and was alive 2 years after her first attendance at hospital, but she died shortly afterwards.

Case 3.—W. J., a male aged 65 years, complained of indigestion, anorexia, vomiting, abdominal discomfort, and marked weight-loss over a period of 12 months.

Examination showed an emaciated dehydrated man, with right-sided abdominal guarding and visible peristalsis.

Investigations showed his haemoglobin to be 10·8 g. per 100 ml. with a white-cell count of 10,000 per mm.^{3} Barium-meal examination showed a grossly distended first and second part of the duodenum proximal to a stenosing lesion (*Fig.* 5).

At operation a tumour was found encircling the third part of the duodenum and invading the superior mesenteric artery. It was unresectable and a duodenojejunostomy was performed. A biopsy was taken and was reported as 'fragments invaded by moderately differentiated adenocarcinoma'. No further treatment was given.

The patient's postoperative progress was uneventful. However, he developed severe anaemia with obstruction and died 3 months after the operation.

DISCUSSION

Incidence.—The incidence of carcinoma of the duodenum is approximately 0·01–0·04 per cent in necropsy studies (Jefferson, 1917; Eger, 1933; Willis, 1948). It comprises 0·3 per cent of all gastro-intestinal carcinomas (Eger, 1933), and 45–47 per cent of carcinomas of the small intestine (Eger, 1933; Hoffman and Pack, 1937; Hancock, 1970).

Site.—The distribution within the duodenum is described with reference to the ampulla (Jefferson, 1917; Mateer and Hartman, 1932), and the figures have varied mainly because of the controversy and difficulty in the determination of the tissue of origin of the periampullary lesions. Earlier authors (Eger, 1933; Berger and Koppelman, 1942) have quoted 60 per cent of the lesions to be periampullary, with the remainder being more common above than below the ampulla. By contrast, more recent authors (Resnik and Cooper, 1958) have quoted 17 per cent as periampullary, the remainder being evenly distributed above and below the ampulla. In this review of 126 cases the distribution was 9·5 per cent supra-ampullary, 48·4 per cent periampullary, and 42·1 per cent infra-ampullary (*Table I*).

Age and Sex.—The age distribution has its peak, as one would expect, in the sixth and seventh decades. The sex distribution shows a marginally increased incidence in women, with a ratio of 3 : 2 (*Table II*), contrary to the high male predominance reported by other authors (Hoffman and Pack, 1937; Serrano and McPeak, 1966).

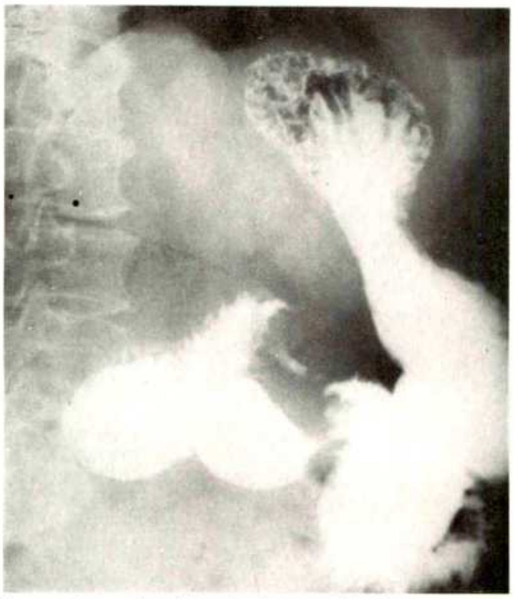

FIG. 4.—*Case* 2. An oblique barium-meal film showing obstruction in the third part of the duodenum.

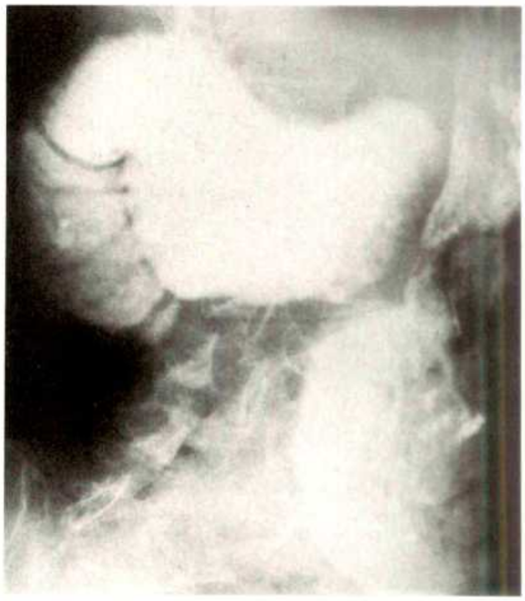

FIG. 5.—*Case* 3. An oblique barium-meal film showing a grossly distended first part of the duodenum with obstruction at the distal end of the second part of the duodenum.

Presenting Symptoms and Signs.—The most common presenting symptoms and signs are those of gastro-intestinal obstruction, abdominal discomfort and pain, weight-loss, and chronic blood-loss leading to anaemia. This was the presentation in the 3 cases described here. Occasionally biliary obstruction or a palpable abdominal mass, as in *Cases* 1 and 2, may be present, but these are late features. Early diagnosis must be based on a high degree of suspicion (Devlin, Platten, and Corrin, 1968). Analysis of 126 cases shows that when these symptoms and signs are clearly manifest there is no significant correlation between duration of symptoms prior to diagnosis and the ultimate prognosis, which probably depends mainly on the biological behaviour of the tumour itself (*Table III*).

Hunt and Ragaz (1965) described a case where the presenting symptoms and signs were those of large-bowel obstruction. Investigations and later operation failed to demonstrate a large-bowel lesion but a duodenal carcinoma was discovered and resected. A similar case was described by Cleator (1970), who considered this to be the result of involvemen of the autonomic nerves around the superior mesenteric artery.

Predisposing Factors.—It is difficult to determine what factors play a part in the development of this disease. The past history of carcinoma of the ovary in *Case* 1 tended to confuse the issue initially. One can only speculate on the significance of this in the aetiology and ultimate prognosis.

The presence of diabetes mellitus in *Case* 1 is also of interest. Diabetes is not associated with a higher incidence of cancer, except for that of the pancreas, where the incidence is tripled or even quadrupled (Karmody and Kyle, 1969). This patient's diabetic state was stable and caused no complications during the operation and in the postoperative period. Control of her diabetes became difficult after radiotherapy but settled with time.

Table IV.—RESULTS OF BARIUM-MEAL EXAMINATION

Result	*No. of Cases*	*Percentage*
Correct diagnosis	31	64·6
Indefinite report	6	12·5
Negative report	7	14·6
Reported as duodenal ulcer	1	
Reported as cancer of pancreas	2	
Total	47	

Despite the frequency of duodenal ulceration only 7 fully substantiated cases of ulcer cancer of the duodenum have been reported (Fawcett, 1966). This contrasts remarkably with the incidence of ulcer cancer of the stomach.

Polyposis of the upper gastro-intestinal tract, unlike that of the large bowel, has always been considered unlikely to undergo malignant change. However, this complacency is unfounded. Twelve cases have been found in a search of the literature where adenocarcinoma had developed directly in or in close association with polyps; of these, 5 occurred in cases of Peutz-Jeghers syndrome (Barclay and Kent, 1962; Horn, Payne, and Fine, 1963; Reid, 1965; Warren, Kune, and Poulantzas, 1965; Williams and Knudsen, 1965). Three cases occurred in siblings with familial polyposis (Ungar, 1949). Two developed as adenocarcinomatous change in benign polyps (Benson, 1963; Andersen, Iversen, and Ostberg, 1965), while the remaining 2 cases were suggestive of adenocarcinomatous change in benign polyps (Devlin and others, 1968).

A recent report suggests that duodenal polyposis in Gardner's syndrome is more common than is realized (Melmed and Bouchier, 1972). They reported 2 cases and from their review of the literature found 4 more. Of these 6 cases, 4 were associated with periampullary adenocarcinoma. The tissue of origin of malignant change, however, was not definitely established.

In view of the above findings it would be interesting and advisable to investigate the upper gastro-intestinal tract of all patients with polyposis.

Diagnosis.—Early diagnosis is extremely difficult for many reasons and relies entirely on suspicion and awareness of this condition. Initial symptoms are vague and are often passed off by the patients without consulting their medical practitioners. Later, more severe symptoms are often confused with those of peptic ulceration, and a period of conservative management with alkalis follows.

A conventional barium-meal examination may not help in the diagnosis as its accuracy is limited and this causes further delay. Where this was recorded in the 126 cases reviewed only 64·6 per cent were diagnosed correctly on a routine barium-meal examination (*Table IV*). All 3 cases in this report were diagnosed late.

The first barium-meal examination in *Case* 2 was reported as normal, but a repeat examination 1 month later, with special posturing, showed the lesion (*Fig.* 4). This emphasizes the difficulty in making an early diagnosis by the conventional barium-meal study, as some areas, especially the third part of the duodenum, are difficult to visualize and may need special posturing. Even so, small lesions can be very difficult to distinguish from the normal mucosal pattern and require special techniques, such as hypotonic duodenography or even coeliac and superior mesenteric angiography (Bosse and Neely, 1969).

The development of duodenoscopy should help greatly in the early diagnosis as it allows direct visualization, photography of the lumen of the duodenum, and biopsy to be performed.

All these sophisticated investigations may be required to distinguish carcinoma of the duodenum from pancreatic carcinoma, ampullary carcinoma, and secondary tumours from adjacent organs. Carcinoid and lymphoma of the small bowel are not rare and Crohn's disease and malignant melanoma have been described in the duodenum. Congenital abnormalities such as diverticula and annular pancreas may confuse the diagnosis.

Management.—A change of attitude in the management of this condition has occurred in the past decade, following the criticism: 'the unusual reticence to attack this lesion aggressively' (Resnik and Cooper, 1958). Operability has increased from 50 per cent a decade ago (Resnik and Cooper, 1958) to 93·4 per cent, and resectability from 43 per cent (Serrano and McPeak, 1966) to 61·7 per cent (*Table V*). Of the present 3 cases, only 1 was resectable and in the remaining 2 a by-pass operation was performed.

In *Case* 1 a segmental resection of the duodenum was carried out even though the tumour extended beyond the confines of the bowel wall and total clearance was not possible. This was done with the hope that reduction in the tumour mass would result in a better response to chemotherapy and radiotherapy. The anatomical anomaly of a separate common bile-duct and pancreatic duct entry into the duodenum increased the difficulty of reimplantation of these ducts. Dissecting them from the duodenum to allow room for anastomosis left the posterior duodenal wall thinned out. This, however, did not produce any difficulties in establishing a conventional two-layer anastomosis. The expected difficulties with reimplantation of the ducts did not occur and at no time in the postoperative period was there any evidence of leakage.

Table V.—TYPES OF OPERATION PERFORMED FOR CARCINOMA OF THE DUODENUM

Operation	*No. of Cases*	*Percentage*
Palliative by-pass	19	31·7
Local resection of lesion	4	61·7
Segmental resection	18	
Pancreaticoduodenectomy	15	
Terminal	4	
Total	60	

In the choice of operation there seems to be little to choose between a local resection and the more radical operation of pancreaticoduodenectomy (*Table VI*). However, a radical resection is strongly advocated, no matter how large or how extensive the tumour might be (Benson, 1963), even if total clearance is not possible. This is good palliation and may bring favourable results when combined with radiotherapy and chemotherapy, as in *Case* 1.

Chemotherapy and radiotherapy have rarely been used in this condition. Apart from *Cases* 1 and 2 there are only 3 other recorded cases in the recent literature.

The lesson learned by Sir Thomas Dunhill in 1927 (Dunhill, 1952), who inserted radium needles in an open operation for a recurrence, has been forgotten until now. The initial response was good, but his patient finally succumbed after 6 months.

It is most interesting to note the prolonged survival of 4 patients who had palliative by-pass operations followed by radiotherapy and chemotherapy (*Table VI*). Two survived for more than 2 years (Spinazzolla and Gillesby, 1963), 1 for 2 years (*Case* 2), and 1 for 4½ years (Serrano and McPeak, 1966). This contrasts markedly with the 15 patients who had by-pass operations alone, as 13 did not survive for more than 1 year and 2 were not followed up adequately (*Table VI*). The good response to radiotherapy seems to indicate that carcinoma of the duodenum is amenable to this form of treatment, contrary to popular belief, and that reluctance in its use is unfounded. With modern radiotherapeutic technique a large dose may be delivered accurately and safely to the area of involvement.

Table VI.—MORTALITY AND SURVIVAL PATTERN COMPARED WITH TYPE OF TREATMENT

Total							
Dead	18	3	7	5	4	—	37
Alive	7	4	5	2	2	3	23

There have been no reports on the postoperative use of radiotherapy and chemotherapy following resection, apart from the present *Case* 1. The patient in this instance has done well and only with increasing use can the full benefit of this procedure be evaluated.

Prognosis.—It is difficult to determine the real prognosis because this series is relatively small and the follow-up of cases has been poor or for too short a period. For this reason a 5-year survival rate would be invalid, but the pattern of mortality and survival

(*Table VI*) may give some guidance in assessing the progress of this disease in relation to its management. There was a 22·2 per cent immediate mortality-rate, i.e., survival of less than 3 months, which accounts mainly for the terminal cases. Most subsequent deaths occurred within the first 2 years, and there were 4 deaths after this period. Three patients survived for more than 5 years, and the speculative assessment of *Table VI* would make the 5-year survival rate much lower than the 22 per cent quoted from the Mayo Clinic in a series of 41 patients (Pagtalunan, Mayo, and Dockerty, 1964).

CONCLUSIONS

Study of the 3 cases presented here together with reports in the recent literature show that carcinoma of the duodenum is slow-growing, late to metastasize and, in a small number of cases, may arise from, or in close association with, intestinal polyps and polyposis.

There does not seem to be any correlation between duration of major symptoms prior to diagnosis and the length of survival. Hence, the emphasis is on early diagnosis and utilization of modern diagnostic techniques to achieve this, as conventional barium-meal examination is only about 65 per cent accurate.

Aggressive surgical management produces the best results even when resection is incomplete, and radiotherapy has a definite place, as in the few cases reported the effect was beneficial and the tumour appeared to be more amenable to radiotherapy than has previously been considered.

Acknowledgements.—We would like to thank Mr. B. S. Ashby for his advice and permission to publish his case. We are grateful to Dr. D. Caldwell for *Fig.* 3 and comments on microscopy of the tumour, and to Mr. J. Wood and the Photography Department of Southend General Hospital for the other photographs. We would like to thank Mrs. J. Bramley for typing the manuscript.

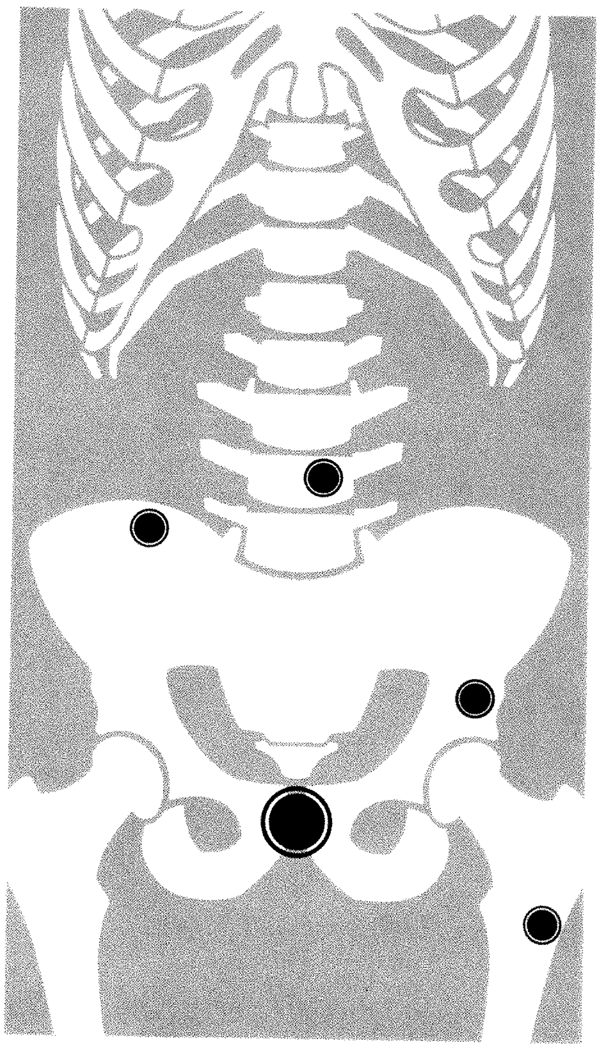
Honvan fosfestrol

Honvan is pharmacologically inert until dephosphorylated. It is selectively activated by tissues rich in acid phosphatase, notably the prostate, where it exerts a local cytotoxic action.

Regression of prostatic tumours and metastases is observed in most patients, including a majority of those unresponsive to standard oestrogen therapy.



Response is rapid. **Honvan** is a practical alternative to surgery in acute urinary retention caused by prostatic carcinoma.

Gastric tolerance of **Honvan** is good and side effects comparatively rare.

Honvan is available for both intravenous and oral administration.

a selective cytotoxic action
- in prostatic carcinoma

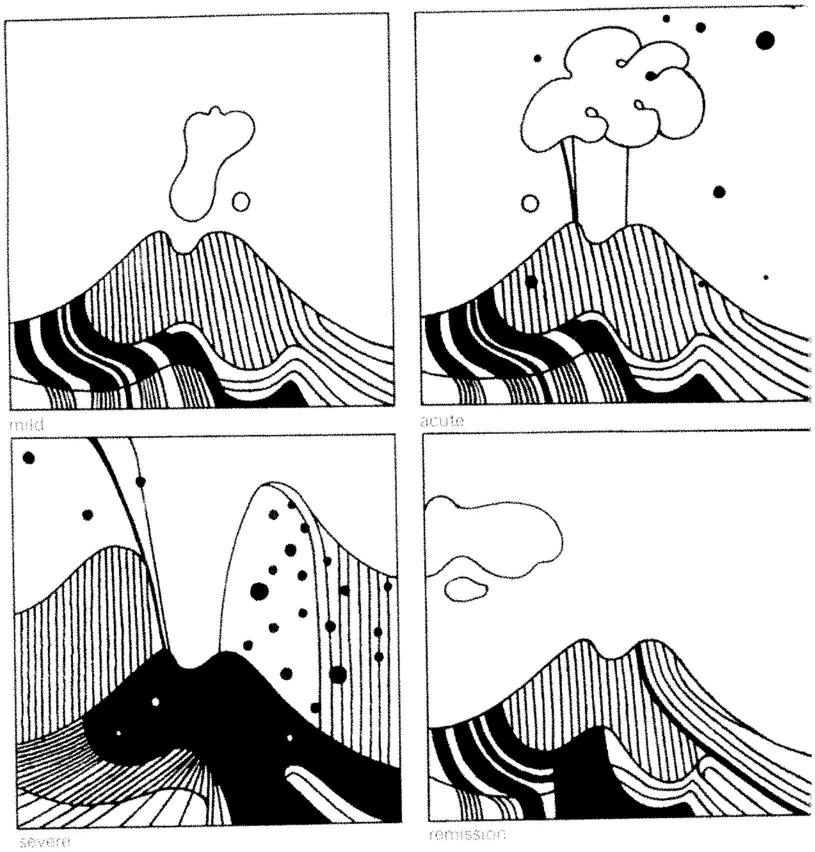
W B

For all stages of Ulcerative Colitis



"Fortunately, Sulphasalazine tablets, 0.5 grams. 4 times a day will prevent relapses in the majority of patients with colitis, and only a few patients cannot tolerate this relatively small dose, which can be continued indefinitely, since we do not know when, if ever, it can be safely stopped."

General Practitioner, April 7 (1972).

In the treatment of the acute attack, sulphasalazine may produce rapid, dramatic improvement in the patient's condition. A similar specific action of sulphasalazine is seen in late post-dysenteric colitis in patients in whom steroid therapy has failed."

Lancet (1973), I, 698

Salazopyrin (sulphasalazine) is available as the plain 0.5g. tablet, 0.5g. EN-tab and as an 0.5g. suppository.

Literature and detailed information on Salazopyrin are available on request.

Salazopyrin is a registered trade mark

CIGARETTE CONSUMPTION AND ATHEROSCLEROSIS

THEIR RELATIONSHIP IN THE AORTA AND ILIAC AND FEMORAL ARTERIES

By G. LAWTON

ROYAL NORTHERN HOSPITAL, LONDON

SUMMARY

The relationship between cigarette consumption and stenotic and occlusive atherosclerotic disease of the lower abdominal aorta and iliac and femoral arteries has been investigated by means of lumbar aortography. Cigarette smoking appears to be associated with atherosclerosis of these vessels. This association seems to be quantitatively related in the lower abdominal aorta, but the relationship is less marked for the iliac vessels and the severity of the disease in the femoral arteries does not appear to be related quantitatively to cigarette consumption. The failure to show a quantitative association in the more peripheral vessels could either be due to limitations and artefacts produced by the method of measurement, or suggest that the atherosclerotic lesions at different levels in the arterial tree are not necessarily homogeneous in nature.

THERE is now a considerable body of information relating to tobacco consumption and atherosclerosis of the coronary arteries. Doyle, Dawber, Kannel, Heslin, and Kahn (1962), Auerbach, Hammond, and Garfunkel (1965), and Strong, McGill, Richards, and Eggen (1966) were among the first to note that the frequency and severity of coronary artery disease were directly related to cigarette consumption. Less has been documented about the relationship of peripheral atherosclerotic vascular disease and cigarette consumption, although Begg (1965), Gomes, Bernatz, and Juergens (1967), and Oldham (1964) have demonstrated that there is a relationship between cigarette consumption and atherosclerotic vascular disease. However, Doll and Hill (1964) were not able to show a heightened risk of arterial disease other than coronary heart disease among British doctors who smoked cigarettes. This contrasts with the findings of Widmer, Hartmann, Duchosal, and Plechl (1969), who reported that arterial occlusions of the limbs and coronary arteries were associated with the same risk factors.

Coran and Warren (1966) have shown that symptoms alone cannot provide reliable information on either the type or the extent of peripheral arterial lesions. Kingsbury (1966) noted that when the disease was considered in terms of arterial lesions, rather than symptoms and signs, there appeared to be some division in the type of disease as well as in its extent, and suggested that atherosclerotic lesions at different sites could not necessarily be considered homogeneous in nature. Study of the radiographs of the aorta and iliac and femoral arteries can allow precise diagnosis and anatomical localization of peripheral atherosclerotic disease and this lends itself to objective reproducible measurement. It would therefore seem possible to compare the lesions of atherosclerotic peripheral vascular disease as seen on radiographs with cigarette consumption and to determine their overall association as well as attempting to define their relationship at different sites in the arterial tree.

MATERIAL AND METHODS

All the patients in this series were referred by clinicians because of symptoms of impaired vascular supply. The series was composed of 41 males and 13 females whose mean ages were 60·3 and 60·2 years respectively. Lumbar aortography was performed by direct needle puncture and consecutive films were obtained using the Garrow Box film changer. Diagnostic films from the aorta to the popliteal artery were obtained. The height of the X-ray tube above the films was constant in all the cases and magnification factors may be considered to be constant. Patients known to have diabetes, hypertension, or polycythaemia were excluded from the series, as were patients who had already undergone vascular surgery and patients in whom there was any doubt that the occlusive or stenotic lesion was primarily due to atherosclerosis. Patients who presented with atherosclerotic abdominal aneurysms were likewise excluded since their condition was not essentially that of occlusive arterial disease. Otherwise, the series consisted of consecutive referrals, and in the patients who later underwent surgery the diagnosis of atherosclerosis was confirmed. All the patients were interviewed before aortography and their smoking habits were recorded as to whether they were cigarette, pipe, cigar, or mixed smokers. The quantity of cigarettes consumed was recorded in four groups: non-smoker, 1–19, 20–29, and over 30 per day. Dramatic changes in consumption within the previous 3 years were ignored, the objective being to obtain as far as possible accurate figures of the patient's lifelong smoking habits. The radiographs were analysed and a series of measurements was taken. Previous workers have described techniques for the analysis of arteriograms but none was considered suitable for this investigation and a new system of analysis was introduced. Routine lumbar aortography only allows appreciation of the arterial system in the postero-anterior plane. It is appreciated that because the vessels are only visualized in one plane, occasional errors of interpretation could occur. However, this procedure has gained general acceptance as a precise means of accurately showing the arterial tree, and findings at operation or autopsy compare well with aortography. An artery which has a minimum cross-sectional diameter equal to half of its maximum cross-sectional diameter has its calibre reduced by half in the postero-anterior plane and has a minimum : maximum ratio of 0·5. This minimum : maximum ratio is equivalent to the 'available' artery remaining, and a severely stenosed artery would thus have a low reading whilst an unaffected artery would have a reading approaching 1·00. An occluded artery has a reading of zero. Measurements of the internal diameters of the vessels were taken at their minimum and maximum cross-sectional diameters for each artery. The lower abdominal aorta was considered to be too long a segment to be treated as one artery and two arbitrary lines were drawn at the lower border of the second lumbar vertebra and at the lower border of the third lumbar vertebra. One set of minimum and maximum diameters of the aorta was taken between the lower border of the second lumbar vertebra and the lower border of the third lumbar vertebra. This is referred to as the aorta opposite lumbar vertebra 3. A second set of minimum and maximum diameters of the aorta was taken between the lower border of the third lumbar vertebra to the aortic bifurcation. This is referred to as the aorta opposite lumbar vertebra 4. An example of the method used is illustrated in *Fig.* 1. The radiographs of a random sample of the cases were examined 'blind' by a second person who was unaware of the age or tobacco consumption of the patients in order to determine the reproducibility of the measurements.

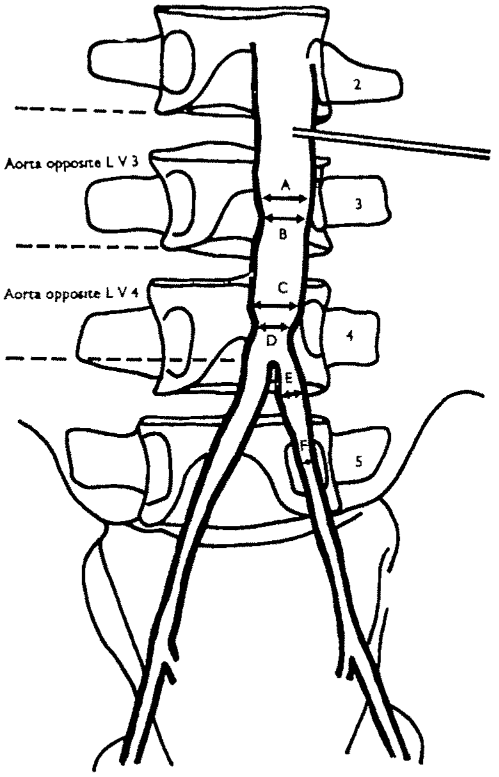

FIG. 1.—An illustrative example of the method used to determine measurements and ratios described in the text. For the aorta opposite L.V.3, A = maximum aortic measurement = 26 mm. and B = minimum aortic measurement = 20 mm., therefore the minimum : maximum ratio opposite L.V.3 is 20 : 26 or 0·77. For the aorta opposite L.V.4, C = maximum aortic measurement = 22 mm. and D = minimum aortic measurement = 16 mm.; therefore the minimum : maximum ratio opposite L.V.4 is 16 : 22 or 0·73. For the left common iliac artery, E = maximum measurement = 11 mm. and F = minimum measurement = 7 mm.; therefore the minimum : maximum ratio is 7 : 11 or 0·64. The ratios for the right common iliac, the external iliac, common femoral, and superficial femoral arteries are obtained in the same manner.

RESULTS

A total of 56 patients was studied, consisting of 41 males and 15 females. All the male patients smoked cigarettes and 6 of these also smoked cigars or pipes or both. Two of the females were life-long non-smokers and were not included in the quantitative assessment since this additional group would have been too small to give valid data for study. *Table I* shows a paucity of relatively light smokers (1–19 cigarettes per day) in the youngest age-group, and it seems that, in general, the heaviest smokers (over 20 cigarettes per day) were younger. *Table II* shows the expected minimum : maximum ratio measurement at the mean age for each group of cigarette smokers. The statistical technique used to estimate and test the ratios in *Table II* was analysis of covariance. The results for both groups of aortic measurements are significant ($P < 0·01$) and show that when related to age the heaviest smokers have the most severe atheromatous stenotic lesions. The ratios for the common iliac artery also show that the heaviest smokers have the most severe stenoses, but the significance level is lower ($P < 0·05$). The ratios for the external iliac artery show the same general trend of increasing severity of disease with increasing cigarette consumption but this finding is not statistically significant. The ratios in the common and superficial femoral artery appear to be entirely random in distribution and are not related quantitatively to

Table I.—NUMBER OF PATIENTS CLASSIFIED BY NUMBER OF CIGARETTES SMOKED PER DAY AND BY AGE

AGE (yr.)	NO. OF CIGARETTES SMOKED PER DAY			TOTAL NO. OF PATIENTS
	1–19	20–29	30+	
Under 50	0	5	3	8
50–59	4	5	6	15

Superficial femoral artery (left and right)	0·37	0·28	0·32	N.S.

N.S., Not significant.

increasing use of cigarettes. A standard statistical program (B.M.D. X64: Bio-medical Computer Programs, X-series Supplement, University of California Press, 1970) was used to do the computation. The radiographs of 5 patients (the sample chosen by using tables of random numbers) were analysed and measured by a second person 'blind' to the figures obtained by the first. This involved 100 measurements at 50 sites. A comparison of the results showed disagreement by a margin of over 0·10 in only 6 per cent of cases, and in 60 per cent of the measurements the margin of disagreement was not more than 0·03. The area of greatest disagreement was in the measurements in the more distal arteries.

DISCUSSION

The consecutive referrals consisted of 41 males and 15 females, of whom only 13 were included in this quantitative assessment. The male : female ratio is under 3 : 1. This compares with the larger series of Gomes and others (1967) where a 4 : 1 ratio was encountered. The invariable consumption of cigarettes by the male patients has been well documented by Oldham (1964) and Begg (1965), and this compares with the findings of Todd (1969), who noted that only 61 per cent of all men in the United Kingdom were cigarette smokers. Several studies concerned with the relationship of cigarette smoking and atherosclerosis have been carried out on autopsy material by Auerbach and others (1965), Strong and others (1966), and Sackett, Gibson, Bross, and Pickren (1968), for it is difficult to assess the amount of atherosclerosis in living patients (Kingsbury, 1969). It has been suggested by Mainland (1953) that there may be inherent disadvantages in this type of study where there may be strong selective factors that tend to make autopsy series non-representative of the general public. In addition, historical information desired for comparison with autopsy findings may be unavailable.

Other work has been concerned with the follow-up of patients presenting with claudication or gangrene (Oldham, 1964; Begg, 1965), but not all patients had lumbar aortography to assess aorto-iliac disease as well as femoral artery disease. Also, there may have been some patients who were not primarily affected by atherosclerosis. During the collection of the present series, patients were excluded on the grounds of emboli, aortitis, thrombo-angiitis obliterans, and fibromuscular arterial disease. It is not suggested that the appearance of this group of patients with non-atherosclerotic arterial disease is in any way representative other than reflecting clinician interest. Diabetic, hypertensive, and polycythaemic patients were also excluded from the series since these patients have been shown by Gomes and others (1967) to be associated with increased risk factors in peripheral vascular disease. Steinberg, Archer, and Steinberg (1965) were the first to attempt systematic measurements of the normal and diseased aorta. Morton, Ehrenfeld, and Wylie (1967) devised a scoring system based on arterial blocks. Kingsbury (1969) showed that it was not possible to group atherosclerotic plaques naturally into representative shapes or sizes and he attempted to grade the severity, type, and extent of atherosclerotic peripheral disease also on a scoring system. However, it was felt that these methods of scoring were not acceptable in this study in that each artery was not individually measured, and also it was thought that the previous scoring systems could not be as accurate for this particular study as the method devised. Kingsbury (1969) suggested that there might be differences in extent and type of atheroma and he noted that blood-sugar concentrations (but not plasma-cholesterol levels) differed according to the distribution of the main arterial lesion, being higher in aorto-iliac disease than in femoropopliteal disease. Studies of both the epidemiology and pathology by Morris (1951) and Mitchell and Schwartz (1965) suggested that atherosclerosis is not necessarily a uniform disease.

There are a number of areas in this study where error in data collection or assessment might have occurred. First, there is possible bias through case selection. In general, surgeons are now less prepared to operate on stenotic or occlusive lesions below the inguinal ligament and will tend to refer for aortography only the patients whose disease clinically is predominantly in the aorto-iliac region. There might be some factors in these patients which differ from those whose disease is more peripheral. Secondly, there is possible bias in smoking assessment. All the patients were examined by the same person and a formal questionnaire was used. Thirdly, the measurements might be inaccurate, but from the sample of radiographs examined 'blind' by a second person there was little disagreement in the figures obtained for the proximal arteries although some disagreement occurred in the more distal arteries. This suggests that any inaccuracies of measurement are only of importance in the more peripheral arteries. In the smaller arteries, measurement differences of 1 mm. may have a profound effect on the minimum : maximum ratio, and it is therefore possible that this ratio is a much better measure of disease (and hence its smoking association) in larger arteries and that the smaller peripheral arteries are not capable of being assessed accurately by the method used here. However, it is difficult to see any modification which might allow more accurate assessment. It is also possible that the apparent absence of an association between smoking and disease of the superficial femoral artery might be because of gross end-stage disease and that an earlier effect is obliterated as the artery becomes blocked. Although this is probably the case, it was noted that there was no apparent quantitative association between atherosclerosis in the common femoral artery and smoking. This artery was only rarely occluded and had a relatively high ratio. A fourth possibility which could affect the assessment of the results is the effect of proximal stenosis on distal calibre. It is not always possible to know whether the whole lumen of an artery distal to an obstruction has been filled by contrast material. Where there is a tight proximal stenosis with a big pressure drop the contrast material often does not fill out the entire arterial lumen. This factor clearly could affect the measurements obtained. It is stressed, however, that it is not suggested that the diameters measured or the ratios obtained are in any way related to flow or pressure. In spite of all these errors which might occur during the collection of the results it is thought probable that the figures obtained reflect the quantitative association of atherosclerosis with smoking. This association appears to be maximal in the aorta and becomes less apparent distally, either because of inaccuracies in measurement hiding a true association or, less likely, because of differences in the homogeneity of atherosclerosis.

THE 'ICED-GLOVE' METHOD OF TREATMENT OF PARAPHIMOSIS

BY G. R. HOUGHTON
NUFFIELD DEPARTMENT OF SURGERY, RADCLIFFE INFIRMARY, OXFORD

SUMMARY

A new method of reduction of paraphimosis, using a rubber glove filled with iced water, is described. The method is simple to carry out and causes little discomfort to the patient. Successful reduction was performed in 9 out of 10 cases, often when manual reduction had failed. Reasons for the single failure are put forward, and alternative treatment is suggested for such complicated cases.

PARAPHIMOSIS may occur at any age. The patient usually presents for treatment before venous engorgement of the glans has resulted in anoxic ulceration and infection. Early reduction is necessary to prevent these changes.

Manual reduction by compression of the oedematous tissues and manipulation of the constricting band over the glans penis (Schenck, 1930) is often successful but without a general anaesthetic is extremely painful. This method may be facilitated by lubrication with Vaseline and the application of ice packs to lessen the oedema. If the method fails other procedures which can be tried include the injection of hyaluronidase to dissipate oedema (Ratcliff, 1954), drainage of oedema by Southey's tubes (Barry, 1954), a dorsal slit of the constricting band (Schenck, 1930), immediate circumcision (Cletsoway and Lewis, 1957), excision of the constricting band (Cumston, 1920), or reduction of the constricting band with Babcock clamps (Skoglund and Chapman, 1970). All these methods require skin puncture or incision into, or application of clamps on to, an oedematous area which will increase inflammation in damaged tissues. A general anaesthetic is often required because operative techniques are painful.

In this paper a simple method is described to reduce the paraphimosis without incising or puncturing the skin using local pressure and ice.

METHOD

The glans penis and oedematous fold of foreskin are coated with anaesthetic jelly (e.g., xylocaine gel), both to lubricate and to anaesthetize the area. After 2 minutes surface anaesthesia is complete. A disposable No. 8 rubber glove is half filled with ice and water and a knot is tied in the cuff to prevent the contents from escaping (just as one would tie off the spout of a toy balloon). The fingers may also be tied so that the contents are confined to the body of the glove. The prepuce is fully retracted, and the glans is placed into the thumb of the glove which is held invaginated by the operator (*Fig.* 1). The distended glove is pressed on to the pubis by the surgeon and held in place for 5 minutes, or until the oedema has resolved (*Fig.* 2). A combination of ice cooling together with compression from the thumb of the glove causes a reduction of oedema. The paraphimosis can usually be reduced without difficulty by pushing the constricting band over the contracted glans. Reduction can often be performed through the glove as a 'closed' procedure, but if this fails it is carried out as soon as the glove is removed.

RESULTS

The 'iced-glove' method of reduction of paraphimosis has been performed on 10 consecutive cases presenting at the Radcliffe Infirmary. Their ages ranged from 8 to 91 years and the duration of the paraphimosis varied from 8 hours to 4 weeks (*Table I*).

In 9 cases painless reduction was successfully performed. In 6 of these patients attempts at the standard manual reduction by a general practitioner or casualty officer had failed.

In 1 case the patient had chronic balanitis, which was complicated by a paraphimosis of 3 days' duration. There was severe ulceration of the glans and adhesions between the constricting band and the penile sulcus. These changes made it impossible to reduce the paraphimosis by conservative means, and the 'iced-glove' method failed. A dorsal slit with division of the adhesions under general anaesthetic was successfully performed.

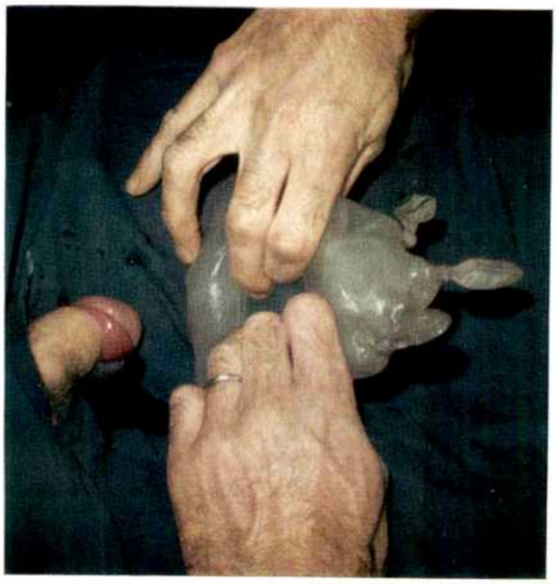

FIG. 1.—Invaginated thumb of the glove about to be stretched over the paraphimosis.

Table I.—SUMMARY OF THE CASES IN THE PRESENT SERIES

CASE No.	AGE (yr.)	DURATION	PREVIOUS ATTEMPTS AT REDUCTION	'ICED-GLOVE' METHOD
1	78	12 hr.	None	Success
2	8	16 hr.	None	Success
3	88	4 d.	Manual reduction failed	Success
4	81	1 d.	Manual reduction failed	Success
5	18	30 hr.	Manual reduction failed	Success
6	23	36 hr.	Manual reduction failed	Success
7	91	4 wk.	Manual reduction failed	Success
8	68	3 d.	None	Failed
9	42	2 d.	None	Success
10	17	3 d.	Manual reduction failed	Success

DISCUSSION

The success of the 'iced-glove' method of reduction of paraphimosis depends upon both pain relief and dissipation of oedema. Surface anaesthesia is established by the local application of xylocaine gel to the glans penis and oedematous foreskin. A gauze swab wrapped around the oedematous tissues ensures that the melting gel remains in place for 2 minutes, by which time surface anaesthesia is usually well established.

Application of the glove is a painless procedure, and it is greatly facilitated by the lubricant action of the gel. Anaesthesia is potentiated by the ice and subsequent reduction of the paraphimosis can be carried out with little discomfort.

As the ice is enclosed within a glove the patient is not distressed by ice-cold water dribbling over the perineum and thighs, which is unavoidable if plain ice packs are applied.

However, in the case with a badly scarred and ulcerated paraphimosis the 'iced-glove' method caused discomfort and failed to cure the condition. In a long-standing and scarred paraphimosis it may be impossible to effect reduction by manipulation, owing to fibrous adhesions between the constricting band and the penile sulcus. In such cases the 'iced-glove' technique is contra-indicated and operative reduction such as a dorsal slit should be immediately undertaken.

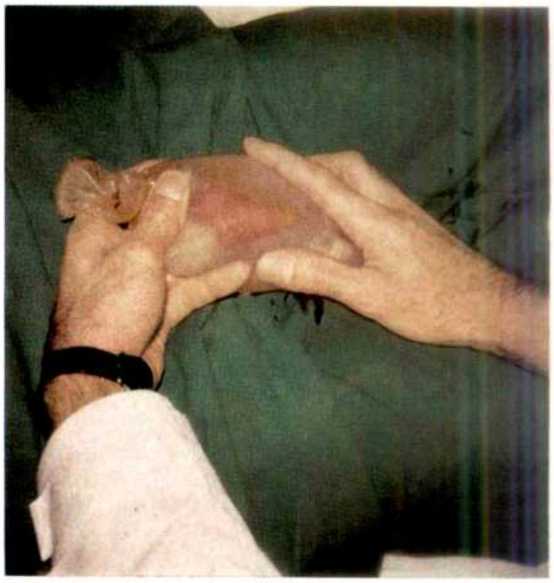

FIG. 2.—Glove in place during compression of the glans.

CONCLUSION

The 'iced-glove' method of reduction of paraphimosis is a successful and painless procedure. It is superior to the standard methods of reduction, but is not recommeded in the presence of ulceration and scarring of the glans.

Acknowledgement.—I am very grateful to Mr. Emanoel Lee for his advice and critical reading of the manuscript.

LUMBAR SYMPATHECTOMY

A RETROSPECTIVE STUDY OF 142 OPERATIONS ON 100 PATIENTS

By J. C. POSTLETHWAITE
ST. MARY'S HOSPITAL, LONDON

SUMMARY

A retrospective survey of 142 lumbar sympathectomies has shown that this operation is of value in the treatment of rest pain and ischaemic ulceration, especially in the 61–70 age-group. It is of less value in claudication. Diabetics fare only slightly less well than non-diabetics. Two cases of ureteric injury are described. Neuralgia occurred in 12·6 per cent of patients.

LUMBAR sympathectomy is one of the commonest operations performed for ischaemia of the feet. The rationale is that there is a high level of vasoconstrictor tone in the circulation of the skin of the foot in contrast to that of the muscle of the calf (Myers and Irvine, 1966b), and that sympathetic denervation results in marked vasodilatation in the foot in the experimental animal (Lövsing and Mellander, 1956) and in man (Walker, Lynn, and Barcroft, 1950).

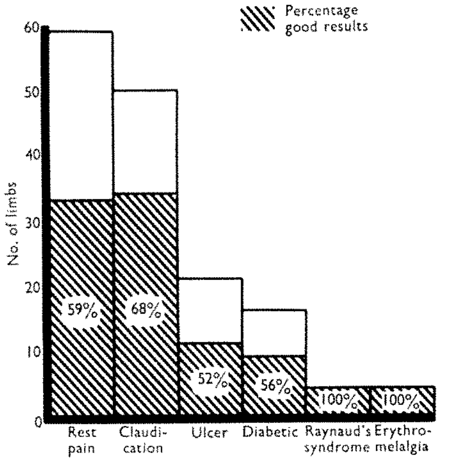

FIG. 1.—Response to lumbar sympathectomy compared with the indications for operation.

The rationale of sympathectomy for intermittent claudication is more obscure (Myers and Irvine, 1966a). Sympathectomy is, however, often performed for the relief of claudication, although its value is disputed (Taylor and Calo, 1962). The main arguments for its use are that some cases in which direct arterial surgery is contra-indicated seem to gain considerable relief of symptoms, and that if done early in the progress of arterial disease it may defer the onset of rest pain and gangrene.

Experienced vascular surgeons generally regard sympathectomy as a safe and simple operation which is relatively free from serious complications. It must be remembered, however, that complications do occur, and that the success of the operation depends upon its proper execution. The present study examines the success of sympathectomy in a London teaching hospital over a period of 5 years with particular reference to the indications, age of patients, complications, subsequent amputation, diabetes, and histology of the sympathetic chain removed at operation.

INDICATIONS

Of the 142 sympathectomies performed, 59 were for rest pain, 20 for ischaemic ulceration, and 51 for claudication. The remainder were for Raynaud's syndrome (4), erythromelalgia (4), acrocyanosis (2), traumatic ulcer (1), and undiagnosed foot pain (1).

OPERATIONS

Fifty-four operations were performed by consultants and 88 by registrars. That sympathectomy is an operation so often entrusted to junior staff is a further, perhaps unsaid, advantage of the procedure.

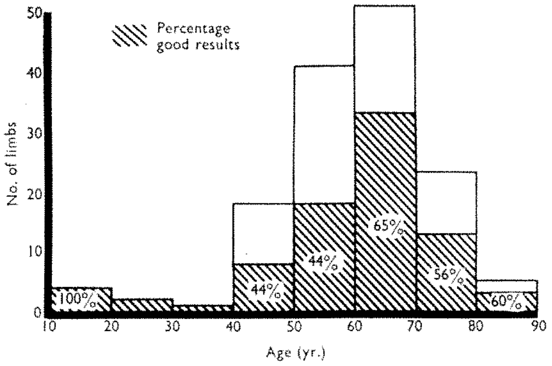

FIG. 2.—Response to lumbar sympathectomy compared with age.

RESULTS

Results of the operation were classified as 'good' or 'bad'. Good results were those in which the patient stated unequivocally that he was improved after the procedure or in which skin lesions were seen to heal. All other responses were classified as bad, since anything but obvious success must be regarded as failure for an elective operation for a specific symptom. In *Figs.* 1 and 2 response is related to the indications and age. Fifty-nine per cent of the patients with rest pain were relieved. This figure falls at the upper end of the usually quoted range of success in rest-pain relief (Berry, Flotte, and Coller, 1955; Gillespie, 1960). An unusually high success rate of 68 per cent was obtained in patients treated in this series for intermittent claudication. The quoted incidence of improvement varies from 13 per cent (Gillespie, 1960) to 75 per cent (Smithwick, 1957). Taylor and Calo (1962) found that 39 per cent of untreated cases improved compared with 41 per cent of cases treated by sympathectomy.

Ischaemic ulceration improved in just over half of the patients treated.

Diabetics fared only slightly less well than the non-diabetic patients.

The response in Raynaud's syndrome and erythromelalgia was excellent, although the numbers involved do not give results of significance.

Age appeared to have a significant effect upon the response to sympathectomy. The 61–70 age-group had a higher success rate than other age-groups over 40 years, in spite of a similar distribution of the various indications. The small number of patients treated for vasospastic as distinct from degenerative disease occurred mainly in the under 40 age-group and had excellent results.

COMPLICATIONS

Post-sympathectomy neuralgia was the most troublesome complication, occurring after 12·6 per cent of operations in this series. Martin, Lynn, Dible, and Aird (1956) stated that the incidence was about 12 per cent, and Tracy and Cockett cited 18 per cent (1957). Four patients with bilateral sympathectomy suffered from neuralgia in only one limb. In a review by Cooley and Herman (1963) the range of incidence of neuralgia is quoted as 2–100 per cent, depending on how thoroughly it is sought. Those authors stated that ligation of the cut ends of the sympathetic chain abolished post-sympathetic neuralgia in 50 cases. Litwin (1962) has reviewed the theories of aetiology of neuralgia, and Silverstein and Jacobson (1967) have discussed the neurological findings. However, no satisfactory explanations have emerged. The clinical findings can largely be explained by postulating a chemical stimulation of somatic afferent fibres by the degenerating myelin of severed fibres of the white rami communicantes. This would explain the delayed onset, spontaneous resolution, and upper lumbar distribution.

Ureteric injury occurred in 2 cases. In one patient with extensive scarring due to an old psoas abscess the injury was recognized at the time of operation and was successfully repaired. The other case presented with ureteric bleeding 1 week after sympathectomy and required nephrectomy.

Ileus occurred in 4 patients, 2 of whom had had bilateral sympathectomy at the same operation.

One deep-vein thrombosis and one myocardial infarction occurred.

There was 1 death in an elderly patient.

HISTOLOGY

The histology of the removed sympathetic chain proved negative in 9 cases (7 performed by registrars and 2 by consultants). The response to surgery was good in 55 per cent of these cases (58 per cent overall), suggesting either the unreliability of subjective responses or that the sympathetic chain was removed but not seen on microscopy.

SUBSEQUENT AMPUTATION

Major amputation following sympathectomy was required in 15 per cent of the limbs in this series. Amputation was usually a relatively early event, being required within 6 months of sympathectomy in most cases. The possible explanation for this is that sympathectomy has little effect on rapidly progressive arterial disease or established gangrene (Taylor and Calo, 1962), but that it significantly reduces the risk of development of gangrene (Edwards and Crane, 1961).

CONCLUSIONS

Lumbar sympathectomy retains an important place in the treatment of ischaemia of the feet, and is of undoubted value in the relief of rest pain and the promotion of healing of ischaemic ulceration. It probably delays the development of gangrene, but has little value in the treatment of established gangrene, those limbs requiring amputation coming quickly to this procedure. In this series, sympathectomy appeared to improve intermittent claudication, even taking into account the natural tendency for this symptom to improve in some instances.

The complication rate is low, although neuralgia causes appreciable postoperative disability. However, although this is difficult to treat, it is self-limiting. The mortality and incidence of serious cardiorespiratory complications are low.

Two cases of ureteric injury in 100 patients highlight the dangers of sympathectomy and are a reminder of the necessity to identify the ureter and to check its integrity before closure of the wound (Higgins, 1967).

Diabetes has little adverse influence on the effectiveness of sympathectomy.

EFFECT OF CORPORAL AND ANTRAL GASTROJEJUNOSTOMY ON CANINE GASTRIC EMPTYING OF SOLID SPHERES AND LIQUIDS

By KEITH A. KELLY, KENNETH D. MORLEY*, AND BRUCE G. WILBUR†

DEPARTMENT OF SURGERY, MAYO CLINIC, AND THE MAYO MEDICAL SCHOOL, ROCHESTER, MINNESOTA

SUMMARY

Gastric emptying of solids and liquids was measured in 12 dogs with and without corporal or antral gastrojejunostomy. Both types of stoma hastened the onset but did not alter the time from onset to complete emptying of 40 small plastic spheres. Corporal gastrojejunostomy slowed the emptying of 400 ml. of 154 mM NaCl but not of 500 mM glucose, whereas antral gastrojejunostomy slowed the emptying of both.

GASTRO-ENTEROSTOMY has been used by surgeons to alter gastric emptying for almost 100 years (Wölfler [1881], 1962). The assumption often made is that the operation speeds the discharge of gastric content from the stomach. However, no quantitative assessment of gastric emptying of solids and liquids after gastro-enterostomy has been done.

We tested the effect of corporal and antral gastrojejunostomy on gastric emptying of solid spheres and liquids in conscious dogs and found that the rate of emptying was not increased. In fact, gastric emptying of iso-osmolar NaCl was slowed.

MATERIALS AND METHODS

Twelve mongrel female dogs, weighing 8–15 kg., were divided into two groups. Four dogs underwent immediate gastrojejunostomy under sodium pentobarbital anaesthesia using sterile technique, and 8 were not operated on. The stomach and jejunum were exposed through a ventral midline upper abdominal incision. In dogs 1 and 2 a longitudinal gastrotomy was made through the anterior wall of the stomach parallel to the greater curvature and 1 cm. from it; the incision began 16 cm. orad to the gastroduodenal junction and extended aborad 4 cm. A longitudinal jejunotomy was next made through the antimesenteric border of the proximal jejunum; the incision began 15 cm. distal to the ligament of Treitz and extended aborad 4 cm. An antecolic anastomosis was then performed between the stomach and the jejunum at the enterotomy sites using a single layer of non-inverting, interrupted, 000 Dacron sutures. The stomach and jejunum were joined so that the orad limits of the gastrotomy and jejunotomy were apposed, as were the aborad limits. Thus, an isoperistaltic, antecolic, anterior, corporal gastrojejunostomy resulted, with a circumference of 8 cm. and a diameter of about 2·5 cm. The most distal limit of the anastomosis was 12 cm. from the gastroduodenal junction. Silver clips were placed at the anastomosis to facilitate its later fluorographic identification.

Identical techniques were used in dogs 7 and 8 to fashion an antral gastrojejunostomy, with the distal limit of the anastomosis 2 cm. from the gastroduodenal junction.

The dogs that underwent operation were allowed 2 weeks to recover, after which emptying tests were begun. Each dog was fully conscious during every test and had been fasted for 18–24 hours. The stomach was aspirated using an oral gastric tube and then washed with 200 ml. of water 30 minutes before the start of any test. If gross amounts of food or particulate matter were found in the aspirate or wash the dog was not used on that day. If small amounts were found the stomach was washed with 100-ml. aliquots of water until it was clear, and the dog was allowed to rest for at least 3 hours before testing.

Gastric emptying of solids was measured five times in each dog, using 40 radio-opaque solid spheres made of polypropylene, each with a diameter of 7 mm. and a specific gravity of about 1·02. The spheres were placed into the stomach via an oral gastric tube, which was then removed. The number of spheres that emptied from the stomach was counted fluoroscopically every 20 minutes, until all the spheres had emptied or 8 hours had passed. The pattern of gastric and intestinal contractions was also noted, and, on some occasions, cinefluorography was performed to obtain films of the movements. The use of spheres by our laboratory to monitor gastric emptying of solids has been described previously (Schlegel, Coburn, and Code, 1966).

Gastric emptying of liquids was assessed on four or five occasions in each dog. The dogs stood or rested comfortably in a Pavlov sling. An oral gastric tube was inserted, and 400 ml. of 154 mM NaCl with 0·00035 per cent of 1,2-^{14}C-polyethylene glycol (^{14}C-PEG; New England Nuclear) of specific activity 0·6 μc. per g. were instilled into the stomach during a period of 20–30 seconds. The tube was then removed. When administered the instillate was at 37·5° C. and had a pH of approximately 6·5. Fifteen minutes after instillation the gastric tube was reinserted and the gastric content was removed by siphoning and gentle aspiration with a syringe. The stomach was washed with 100 ml. of NaCl, and the wash was aspirated to recover any residual instillate.

At the completion of each test the volume of gastric aspirate and gastric wash recovered was measured. The specific activities of 5-ml. samples of aspirate, wash, and original instillate were determined using a liquid scintillation spectrometer (Packard TriCarb 3375). The volume of the instillate remaining in the stomach after 15 minutes was then calculated using the following formula:—

* Visiting Medical Student, University of Aberdeen, Scotland.

† Research Assistant, Surgical Research.

$$V_R = V_A\left(\frac{SA_A}{SA_I}\right) + V_W\left(\frac{SA_W}{SA_I}\right),$$

in which V_R is the volume (ml.) of the original instillate remaining in the stomach after 15 minutes, V_A is the volume (ml.) of the gastric aspirate, V_W is the volume (ml.) of the gastric wash, and SA_I, SA_A, and SA_W are the specific activities of the instillate, gastric aspirate, and gastric wash, respectively.

A third set of experiments performed four or five times in each dog was done in an identical fashion, except that a 400-ml. instillate of 500 mM glucose was used instead of the NaCl instillate, and the stomach was washed with 100 ml. of distilled water.

In a final set of tests, serum gastrin was measured by use of a radio-immunoassay technique (Yalow and Berson, 1970) in 4 dogs without stomas, in 2 with corporal gastrojejunostomy, and in 2 with antral gastrojejunostomy before and 15 minutes after instillation of 400 ml. of 154 mM NaCl.

Usually only one test of gastric emptying was performed on a dog per day. However, on some occasions, two tests a day were done. At least 3 hours separated the two tests when a liquid instillate preceded the administration of spheres or when two saline instillates were given, and at least 5 hours separated the two tests when glucose instillates were given.

After the initial experiments were completed the dogs with gastro-enterostomy were reoperated on, the stomas, which were well healed, patent, and had a diameter of at least 2·5 cm., were removed, and the enterotomies were closed. The dogs who had not been previously operated on then underwent corporal gastrojejunostomy (dogs 3–6) or antral gastrojejunostomy (dogs 9–12). Beginning 2 weeks after operation, the tests of the gastric emptying of solids and liquids were repeated.

RESULTS

All the dogs survived the operations without complications and were well healed after 2 weeks. The dogs with corporal gastrojejunostomy, however, ate poorly, often vomited, and 3 of the 6 dogs lost weight (dogs 3, 4, and 6). They carried a bile-stained, thick, gastric residue of about 100 ml. after an 18-hour fast. Dogs 3 and 6 became very weak, vomited, and aspirated gastric content, and died 5 weeks after the construction of the stoma. The remaining 4 dogs survived until sacrificed 4–6 months later.

The dogs with antral gastrojejunostomy remained healthy and maintained their weight throughout the experiment.

Dogs without a Stoma.—The pattern of emptying of solid spheres and liquids in dogs without a stoma was the same whether the dogs were investigated after the removal of the stoma (dogs 1, 2, 7, and 8) or before the construction of the stoma (dogs 3–6 and 9–12). Therefore, the data on all the dogs without a stoma are considered together.

Gastric Emptying of Spheres.—The overall pattern of gastric movement of spheres in dogs without a stoma was one of retention of the spheres in the antrum, with continuous mixing and grinding interspersed between periodic bursts of emptying (*Fig.* 1).

The spheres passed through the oral gastric tube directly into the fundus and proximal corpus of the stomach. They were then promptly moved into the distal corpus and antrum, where they usually remained for long periods. The overall mean interval (± S.E.) from insertion to onset of discharge of the spheres from the stomach was 77 ± 13 minutes.

While in the distal stomach the spheres were continuously mixed and ground by peristalsis and the terminal antral contraction. An advancing peristaltic wave propelled the spheres up against the gastroduodenal junction. The spheres were then squeezed by the forceful terminal antral contraction until, unable to pass into the duodenum, they suddenly shot back into the more proximal antrum and distal corpus. This propulsion, squeezing, and retropulsion occurred many times, thoroughly triturating the spheres.

At certain times as a peristaltic wave approached the terminal antrum, bunches of spheres would be moved rapidly from the terminal antrum through the gastroduodenal junction into the duodenum. Sometimes, all 40 spheres would be emptied within a 20-minute period (*Fig.* 1, dogs 1, 7, 8, 9, and 10). However, the overall mean time from onset to completion of gastric emptying was 125 ± 26 minutes.

Once in the small intestine the spheres were usually quickly moved from the duodenum into the jejunum. The caudad rate of movement of the spheres then slowed in the jejunum. Rhythmic jejunal contractions oscillated the spheres back and forth, while moving them gradually and progressively caudad. The spheres never re-entered the stomach from the small intestine.

Gastric Emptying of Liquids.—Iso-osmolar NaCl emptied rapidly from the stomach of dogs without a stoma. Almost half of the 400-ml. instillate had left the stomach after 15 minutes (*Table I*). In contrast, hyperosmolar glucose emptied slowly, so that only about 50 ml. had emptied 15 minutes after instillation (*Table I*).

The gastric aspirates in dogs without a stoma were almost always colourless and were not stained with bile (*Fig.* 2). The mean ratio of disintegrations per minute (dpm) from the ^{14}C-PEG in the aspirate over that in the instillate for 12 randomly selected samples was 0·93 ± 0·02 when NaCl was instilled and 0·92 ± 0·02 when glucose was instilled, showing that the marker had been slightly diluted by gastro-intestinal contents.

Serum Gastrin.—The mean fasting concentration of gastrin in the serum of 4 dogs without a stoma was 194 pg. per ml., and it had not increased 15 minutes after the instillation of 400 ml. of 154 mM NaCl, when it was 192 pg. per ml.

Dogs after Gastro-enterostomy.—The patterns of emptying of solid spheres and liquids after gastro-enterostomy were almost identical whether the stoma was constructed in the corpus or in the antrum.

Gastric Emptying of Spheres.—The overall pattern of emptying of spheres after gastro-enterostomy was that of a rapid onset and steady gradual discharge of spheres from the stomach, in contrast to the retention, then burst-of-emptying pattern noted in dogs without a stoma (*Fig.* 1).

The spheres were promptly moved from the fundus and corpus into the antrum of the dogs with both types of gastrojejunostomy, just as when the dogs had no stoma. Vigorous peristaltic waves and terminal antral contractions then commenced, and these effectively propelled and retropelled the spheres in spite of the presence of the large stoma.

† Except dogs 1, 3, 6, 11, and 12 with stoma and dogs 3, 5, 6, 11, and 12 without stoma, in which $n = 5$. S.E. are between 4 and 16, except in dogs 2, 3, 10, 11, and 12 with stoma in which they were between 19 and 30.

‡ Differs from value without stoma ($P < 0{\cdot}05$, unpaired t-test).

§ Differs from value without stoma ($P < 0{\cdot}05$, paired t-test).

However, in contrast to dogs without a stoma, those with a stoma began almost immediately to empty the spheres from the stomach. The mean interval from insertion to onset of emptying was 13 ± 2 minutes which is much quicker than the 77 minutes required when the dogs had no stoma ($P < 0{\cdot}01$, paired t-test).

The spheres were discharged from the stomach in three different ways. First, the spheres moved from the gastric lumen through the stoma and into the efferent limb of the gastrojejunostomy. When the spheres took this route, they did so not in a burst pattern but in a slow, one-by-one sequence.

Secondly, bunches of spheres also periodically shot through the gastroduodenal junction into the duodenum just as they did when the dogs had no stoma. Once in the duodenum the spheres were swept rapidly around into the proximal jejunum which formed the afferent limb of the gastro-enterostomy. The spheres then either re-entered the stomach via the stoma, completing a full circular movement, or moved past the stoma into the efferent limb of the jejunum and thence caudally into the small intestine. On occasions when the spheres were re-entering the stomach through the stoma, the number of spheres counted in the stomach at a given point was sometimes greater than had been found in the preceding period. The phenomenon occurred at least once in 8 of the 12 dogs with gastro-enterostomy (*Fig.* 1), but happened on only one occasion in dogs without a stoma (dog 4).

Thirdly, the spheres occasionally passed from the stomach through the stoma and into the afferent jejunal limb, moving a very short distance orad in the afferent limb. They then would be quickly propelled back again to the stoma and thence into the stomach or into the efferent limb.

Thus, the emptying of spheres from the stomach was the net result of discharge from the stomach through the stoma and through the gastroduodenal junction, as well as of movement back into the stomach from the jejunum through the stoma. (A film documenting the movement of spheres with and without gastrojejunostomy is available from the authors' laboratory.)

Although the onset of emptying of the spheres occurred sooner after both corporal and antral gastrojejunostomy than when the dogs had no stoma, the time from onset to completion of emptying of the spheres was not altered by either stoma (*Fig.* 1). The overall mean time from onset to complete emptying after gastro-enterostomy of 164 ± 26 minutes did not differ significantly from the mean of 125 minutes found when the dogs had no stoma ($P > 0{\cdot}05$, paired t-test). However, none of the dogs with gastro-enterostomy emptied all 40 spheres from the stomach in 20 minutes as they sometimes did when no stoma was present (*Fig.* 1).

The movement of the spheres in the small intestine distal to the stoma in the dogs with gastrojejunostomy, as in those without, was that of slow, rhythmic, back-and-forth oscillation with progressive caudad migration. Once in the efferent jejunal limb, the spheres did not re-enter the stomach.

Gastric Emptying of Liquids.—Corporal gastrojejunostomy slowed the gastric emptying of iso-osmolar NaCl but not of hyperosmolar glucose (*Table I*). The emptying of glucose was slowed in 3 of 6 dogs with a corporal stoma, but when the group was considered as a whole the difference was not significant. Antral gastrojejunostomy slowed gastric emptying of both NaCl and glucose (*Table I*).

Glucose continued to empty more slowly than NaCl in dogs after both types of gastrojejunostomy, just as it did when the dogs had no gastrojejunostomy (*Table I*, $P < 0{\cdot}01$, paired t-test).

The gastric aspirates from dogs with gastrojejunostomy were always, or nearly always, heavily stained with bile, while aspirates from the same dogs without a stoma were almost always colourless (*Fig.* 2). The mean ratio of dpm in the aspirate to dpm in the instillate for 12 randomly selected samples in dogs with slower gastric emptying of NaCl or glucose after gastro-enterostomy was 0·85 ± 0·02, compared with 0·95 ± 0·02 in identical tests in the same dogs without a stoma. Thus, greater dilution of the marker occurred in these dogs after gastro-enterostomy ($P < 0{\cdot}01$, paired t-test). In contrast, in dogs with unaltered gastric emptying after gastro-enterostomy the mean ratio of dpm in the aspirate to that in the instillate was unchanged at 0·93 ± 0·02.

Serum Gastrin.—The mean serum-gastrin concentration during fasting in dogs with gastro-enterostomy was 189 pg. per ml. and was not greater than that in dogs without a stoma. The mean serum gastrin was not increased 15 minutes after the instillation of NaCl in dogs with a stoma, when it was 187 pg. per ml.

Autopsy Findings.—At autopsy the stomas in the 8 dogs with intact gastro-enterostomy were well healed, patent, and not kinked, showed no ulcers, and had a diameter of 2·5 cm. or more (*Fig.* 3). In the 4 dogs in which stomas had been removed, the sites of closure in the stomach and jejunum were smoothly healed, and no evidence of gastric or intestinal stenosis or obstruction was present.

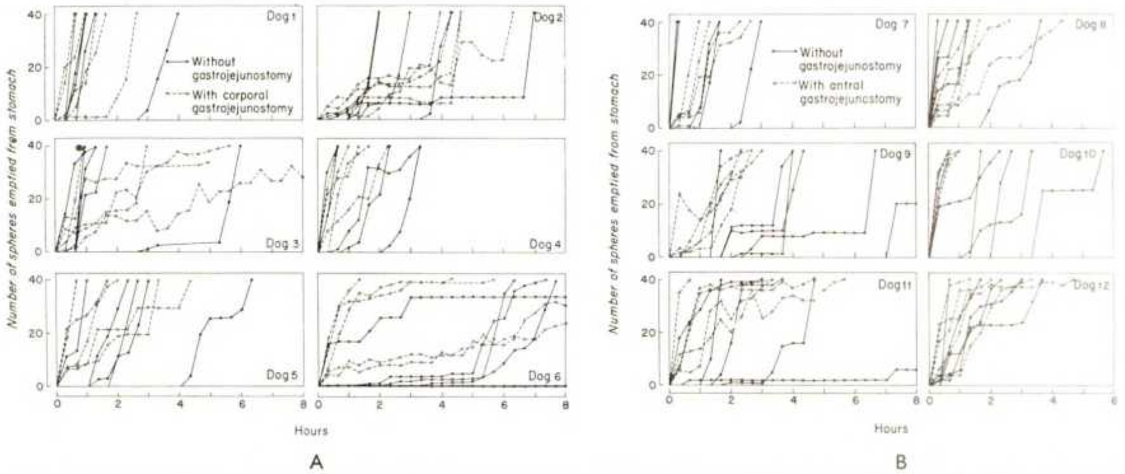

FIG. 1.—Gastro-enterostomy hastens the onset but does not alter the time from onset to complete emptying of 40 plastic spheres. Five tests were done in 6 dogs with and without corporal gastrojejunostomy (A) and in 6 dogs with and without antral gastrojejunostomy (B).

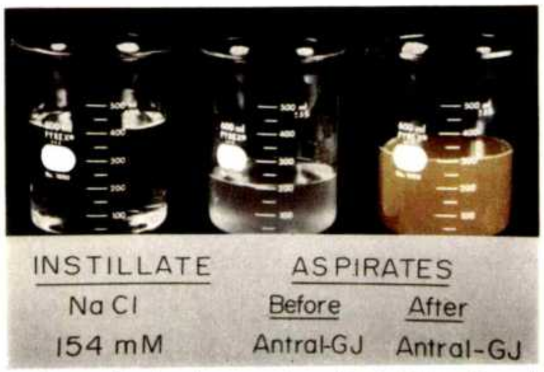

FIG. 2.—Gastric aspirates 15 minutes after instillation of 400 ml. of iso-osmolar NaCl are colourless in dogs without gastro-enterostomy but are bile-stained in dogs with antral (or corporal) gastro-enterostomy. Volume of instillate remaining is greater after gastro-enterostomy (*Table I*).

DISCUSSION

Our experiments have shown that gastro-enterostomy in the dog does not speed gastric emptying of solid spheres and liquids but that it actually slows the emptying of iso-osmolar NaCl.

Cannon and Blake (1905) fed starch gruel or canned salmon mixed with bismuth subnitrate to cats that had corporal or antral gastro-enterostomy, after which they studied gastric emptying fluoroscopically. They found that gastric content, especially the more solid salmon, usually emptied via the gastroduodenal junction rather than via the stoma. They also noted that chyme circulated from the stomach to the duodenum and then back into the stomach again through the stoma. Cannon and Blake, however, did not measure the rate of gastric emptying in their experiments.

Johnston and Ravdin (1935) measured gastric emptying of liquids in dogs with gastro-enterostomy. They instilled solutions of glucose into the stomach and killed their animals 1 hour later. They found greater volumes of fluid in the stomachs of dogs with gastro-enterostomy than in those without. Their instillates were hypertonic, however, and no unabsorbable marker was used. Thus, Johnston and Ravdin could not determine what portion of the volume remaining was instillate and what portion was of gastric or small intestinal origin.

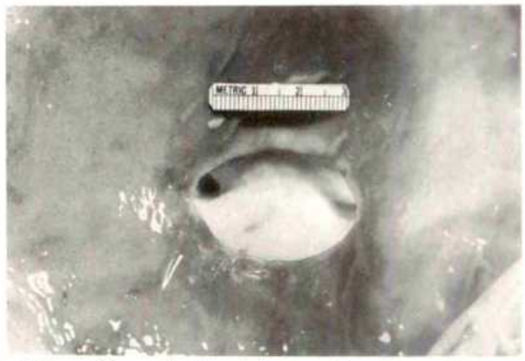

FIG. 3.—Dog 5. A view of the stoma from the gastric lumen at autopsy shows a well-healed gastro-enterostomy with no ulceration or kinks, and a stomal diameter of about 2·5 cm.

In contrast, Gianturco (1934), studying dogs, and Buckler (1967), studying humans, did not find that gastro-enterostomy consistently altered gastric emptying. Neither worker, however, compared gastric emptying in the same subjects before and after gastro-enterostomy.

Our experiments have shown that gastro-enterostomy did not alter the rate of gastric emptying of spheres, but that it did slow the emptying of iso-osmolar NaCl. It is striking that, in spite of the presence of a stoma with a diameter about four times that of the spheres, the net rate of emptying of spheres from the stomach did not differ from that of the controls. We had anticipated, as did Armitage and Dean (1963), that the great pressure generated by gastric contractions, especially in the antrum, would quickly propel the spheres through the large stomas into the jejunum and speed gastric emptying. But this did not happen. The rate of gastric emptying of spheres was not altered by gastro-enterostomy.

An incoordination between gastric and jejunal contractions may have impeded the exit of spheres through the stoma. Weisbrodt, Wiley, Overholt, and Bass (1969) have shown that gastric emptying is impaired if the co-ordinated sequence of gastric contraction–duodenal relaxation is disturbed.

Some spheres did empty in a slow one-by-one sequence through the stoma, and this may account for the earlier onset and the gradual steady pattern of emptying of spheres in dogs with gastro-enterostomy. However, the number of spheres leaving the stomach via the stoma must have been balanced by the number re-entering the stomach, because the overall time of emptying of spheres was unchanged after gastro-enterostomy.

Both corporal and antral gastrojejunostomy slowed gastric emptying of iso-osmolar saline, but only antral gastrojejunostomy slowed emptying of hyperosmolar glucose. However, glucose emptied so slowly in dogs with either type of stoma that the differences were very small.

Since gastrin slows gastric emptying of saline solutions (Hunt and Ramsbottom, 1967), we wondered at first if the slowed emptying of similar solutions that we observed after gastro-enterostomy was partly due to the release of gastrin from the antrum by bile-salts (Bedi, Debas, Gillespie, and Gillespie, 1971; Nahrwold, 1972). Bile was consistently present in the gastric lumen after gastro-enterostomy. However, there was no difference in the amount of gastrin in the serum between dogs with gastro-enterostomy and those without. Thus, bile-salts were not bathing the antral mucosa in concentrations great enough to cause the release of increased amounts of gastrin.

Our experiments show that gastric emptying of liquids is slower after gastro-enterostomy because of the circular movement of gastric content from the stomach to the duodenum and jejunum and back into the stomach again via the stoma. The dilution of the gastric marker, the presence of bile in the aspirated content, and the circular movement of the spheres seen at fluoroscopy after gastro-enterostomy support this interpretation. Thus, the slow emptying is a net result of two opposing fluxes: (1) the discharge of gastric content through the pylorus and through the stoma, and (2) the re-entry of this content into the stomach via the stoma.

It is possible that duodenal content re-entered the stomach by refluxing through the pylorus rather than by passing through the stoma in dogs with gastro-enterostomy. This seems unlikely, however, since we never observed duodenal spheres re-entering the stomach through the pylorus whereas we frequently saw them do so via the stoma.

The braking mechanisms for gastric emptying brought into play by the duodenal osmoreceptors (Hunt, 1963) are still effective after gastro-enterostomy. The emptying of hypertonic glucose remained slower than that of isotonic NaCl in dogs with a stoma. A similar conclusion was reached by Gianturco (1934) and Johnston and Ravdin (1935).

It has been stated that antral gastrojejunostomy leads to more rapid gastric emptying than does corporal gastrojejunostomy (Cannon and Blake, 1905). However, we found little difference in the patterns of emptying between the two types of stomas. The dogs with corporal gastrojejunostomy had a greater gastric residual, vomited more often, and were poorer eaters than those with an antral stoma. Furthermore, 2 of the 6 dogs with a corporal stoma died of aspiration pneumonitis in the post-operative period. We have no satisfactory explanation for these findings. We did not find kinks at the site of the anastomosis, as Cannon and Blake (1905) described.

Gastrojejunostomy has been commonly used in the treatment of duodenal ulcer in the past (Mayo, 1905) and is still employed by some in patients with low outputs of acid (Small, Falconer, Smith, McManus, and Sircus, 1971). The healing effect of the operation, however, has never been explained adequately. The present experiments indicate that the operation may aid the healing of duodenal ulcers by (1) slowing the net rate of emptying of corrosive gastric juices and (2) allowing small intestinal content to enter the stomach where it can buffer and neutralize hydrogen ions.

It should be emphasized that our dogs had no obstruction at the gastroduodenal junction and had intact vagal innervation. When pyloric obstruction or truncal vagotomy has already slowed gastric emptying, gastro-enterostomy may then speed the discharge of gastric content. However, in dogs with a normal stomach the operation does not speed gastric emptying.

Acknowledgements.—Thanks are expressed to Dr. C. F. Code for advice and to Dr. V. L. W. Go who performed the analyses for gastrin.

This investigation was supported in part by Research Grant AM-2015 from the National Institutes of Health, Public Health Service.

First and for all.

In severe neo-natal infections

In septicaemias

In serious post-operative situations

G-DAY-those first vital 24 hours in serious bacterial infections:

- when effective therapy must be initiated to prevent rapid deterioration in the patient's condition
- when the causative organism is unknown or uncertain
- when there is no time for trial and error

When these situations occur in acute or acute on chronic infections, Genticin Injectable, the antibiotic with the broadest bactericidal spectrum of all, has proved eminently successful as first-line therapy in a wide range of conditions.

"It therefore follows that on sensitivity testing alone, gentamicin (Genticin) would be the best single antibiotic for blind chemotherapy."[1]

[1] Reference: J Irish med Ass, 65, No 20, 514, 1972.

Genticin Injectable is available in 2 ml multidose vials and snap-off ampoules. Each 2 ml contains 80 mg gentamicin base as gentamicin sulphate.

Further details are available on request from:
Genticin Technical Service, Slough 23971
Nicholas Laboratories Limited PO Box 17, Slough SL1 4AU

Nolvadex–a more acceptable approach to breast cancer treatment

Drug therapy is often both uncomfortable and distressing for the patient with advanced breast cancer. But now a more acceptable treatment is available for such patients, 'Nolvadex' (tamoxifen).

'Nolvadex' is an oestrogen antagonist. Whilst it is just as effective as other treatments, it has no hormonal properties. Virilization–common with androgens–is unknown; oedema, nausea and vomiting occur much less frequently than with oestrogens.

'Nolvadex' is taken as twice-daily oral doses. So treatment is simple as well as more acceptable.

Further information–including the results of U.K. trials with 'Nolvadex'[1,2] is available on request.

RUPTURED NON-TRAUMATIC ANEURYSMS OF THE DESCENDING THORACIC AORTA

By T. G. J. BRIGHTMORE and C. E. DREW
THORACIC SURGICAL UNIT, WESTMINSTER HOSPITAL, LONDON

SUMMARY

Two cases of ruptured non-traumatic aneurysm of the descending thoracic aorta and a third in which rupture was imminent are discussed with regard to two simple operative techniques, both of which were employed with success. Partial aneurysmectomy was employed in one case and a temporary to permanent shunt graft in the other two. The simplicity of the techniques is such that they may be used in hospitals which are not equipped for extracorporeal perfusion.

THE most common site of aortic aneurysms after the infra-renal abdominal aorta is the descending thoracic aorta (Joyce, Fairbairn, Kincaid, and Juergens, 1964; Bloodwell, Hallman, Beall, Cooley, and De Bakey, 1966; Austen, 1967). The poor prognosis of untreated aneurysms of the thoracic aorta is well documented (Boyd, 1924; Colt, 1927; Kampmeier, 1938; Cranley, Herrmann, and Preuninger, 1954). Their natural history is enlargement and eventually rupture (Groves, 1961) and survival mainly depends on the mode of aneurysm rupture and whether the adjacent tissues, especially the mediastinal pleura, are strong enough to contain the haemorrhage (Bromley, Hobbs, and Robinson, 1965; Valiathan, Weldon, Bender, Topaz, and Gott, 1968).

In dissecting aneurysms rupture is the major cause of death (Hirst, Johns, and Kime, 1958; Wheat, Palmer, Bartley, and Seelman, 1965). Rupture is the cause of death in approximately one-third to one-quarter of patients with syphilitic and arteriosclerotic aneurysms of the thoracic aorta (Cranley and others, 1954; Joyce and others, 1964). In 25 per cent of ruptured syphilitic aneurysms of the thoracic aorta the patient lived for over 6 hours after rupture and 15 per cent of these cases lived for over 25 hours (Cranley and others, 1954). With the more common arteriosclerotic aneurysm death is probably quicker following rupture possibly because of widespread vascular disease.

Factors which have an adverse effect on survival include size of the aneurysm, advanced age, diastolic hypertension, and generalized arteriosclerotic disease (De Bakey, Cooley, Crawford, and Morris, 1958; Joyce and others, 1964). Ching and Hughes (1967) in a clinical series observed an increased incidence of arterial obstructive lesions affecting the brain, heart, and kidneys in patients with arteriosclerotic aneurysm of the thoracic aorta and they concluded from necropsy studies that there was a higher death-rate from causes other than the aneurysm. They recommended a thorough clinical and arteriographic investigation, and because many patients died from myocardial infarction during or after aneurysm

Table I.—DETAILS OF EMERGENCY OPERATIONS FOR RUPTURED ANEURYSMS OF THE DESCENDING THORACIC AORTA REPORTED IN THE LITERATURE

AUTHOR	AGE AND SEX OF PATIENT	SITE OF RUPTURE	TYPE OF SHUNT EMPLOYED	TYPE OF GRAFT	RESULT
Barnard and Schrire (1963)	38 M.	Left lung	Left atriofemoral with moderate hypothermia	Teflon	Died 6 days postoperatively from pulmonary and renal complications and insulin hypersensitivity
	59 M.	Left lung	Left atriofemoral	Teflon	Recovered
Garrett, Ricks, Lewis, Howell, and De Bakey (1965)	62 M.	Left upper lobe bronchus	Left subclavian-femoral	Dacron	Recovered after 2 days' transient hemiparesis
Bryant, Bowlin, Malette, and Danielson (1968)	68 M.	Left main bronchus	Left atriofemoral	Dacron	Died during operation
	61 M.	Left main bronchus	Left atriofemoral	Dacron	Recovered
Valiathan and others (1968)	71 M.	Right chest	Left subclavian-femoral	Dacron	Died 3 weeks postoperatively from myocardial infarction and with ischaemic damage to spinal cord
	55 F.	Left pulmonary artery and left main bronchus	Left subclavian artery to distal thoracic aorta	—	Died during operation
Crawford and others (1970)	65 M.	Not stated	No shunt, aortic cross-clamping	Dacron	Died 2 days postoperatively from cerebrovascular insufficiency
	66 M.	Not stated	No shunt; aortic cross-clamping	Dacron	Died 9 days postoperatively from pulmonary emboli and with paraplegia

resection advised myocardial revascularization, if indicated, prior to aneurysm surgery.

Whatever the merits of advising surgery for intact aneurysms the treatment of ruptured aneurysms is of the utmost urgency. Few patients survive to reach hospital and, of these, only a very few will respond to resuscitative measures and be submitted to operation. The overall results of emergency operations for ruptured aneurysms of the descending thoracic aorta are poor (*Table I*).

The purpose of this paper is to present the successful surgical management of 2 cases of ruptured aneurysm of the descending thoracic aorta and a third in which rupture was imminent.

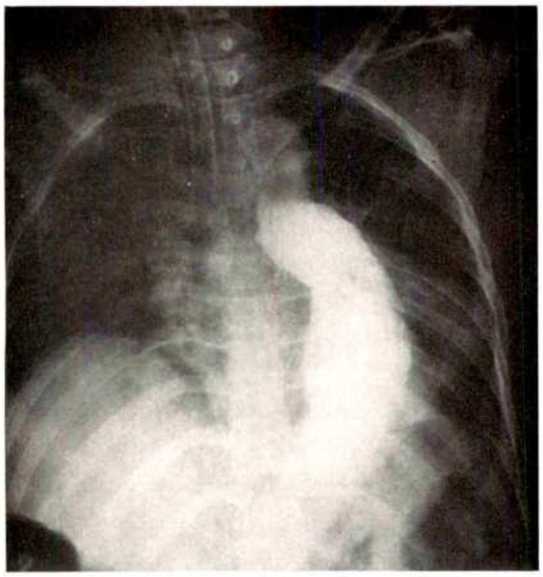

FIG. 1.—*Case* 1. Aortogram showing constrictions and dilatations of the descending thoracic aorta.

CASE REPORTS

Case 1.—A thoracic aortic aneurysm was diagnosed in a 35-year-old male Indian doctor in 1962. In childhood he had had severe hypertension, but following the removal of an ischaemic left kidney when he was 14 his blood-pressure had returned to normal. In May, 1958, at a routine medical examination he was symptomless and normotensive and an intravenous pyelogram had shown a reasonable caliceal pattern. In March, 1960, his blood-pressure was 180/110 mm. Hg. One year later it had risen to 190/120 mm. Hg and retinoscopy had revealed marked arteriolar narrowing. Blood-urea was 55 mg. per cent and the urine contained red and white cells, albumin, and casts. Increase in the aortic shadow was noted on a plain chest radiograph. He was effectively treated with Salupres (reserpine, hydrochlorothiazide, and potassium chloride). He had remained symptomless until October, 1962, when he had severe pain in his left chest and to the left of the thoracic spine accompanied by rigors, a temperature of 40° C., and an erythrocyte-sedimentation rate of 72 mm. per hour. There was a marked increase in the size of the aortic shadow compared with the film taken 18 months previously. A barium-swallow examination demonstrated compression and deviation of the oesophagus. He was referred to the Thoracic Unit at the Westminster Hospital. Aortography revealed an aneurysm of irregular calibre with dilatations and constrictions which extended from immediately distal to the left subclavian artery to the right renal artery—a picture typical of Sen's disease (*Fig.* 1). Function of the remaining kidney was poor as judged by intravenous pyelography and the blood-urea, which was 100 mg. per cent. He was considered unfit for surgery. He had further attacks of severe chest pain and the aneurysm increased in size. On 31 Dec. he had chest pain with haemoptysis, indicating rupture of the aneurysm into the left lung. As a doctor he realized the significance of this symptom and the ultimate outcome. Immediate surgery offered the only prospect of survival, and preparation was made for a left atriofemoral extracorporeal circulation.

The aorta was exposed via a thoraco-abdominal incision resecting the left fourth and ninth ribs. The aneurysm extended from immediately below the left subclavian artery to about 5 cm. above the aortic bifurcation and was a series of constrictions and dilatations, the major sacculation being just above the diaphragm where rupture had occurred into the left lung. The aorta below was uniformly stenosed.

The aorta distal to the left subclavian artery was mobilized and the pericardium was then opened and the left atrium cannulated after heparin had been given. The left femoral artery was similarly cannulated. By-pass was commenced but a large pelvic haematoma was noted with a dramatic fall in blood-pressure, and at this point cardiac arrest was imminent. Dissection of the pelvic vessels had occurred. By-pass was discontinued and the aorta above the aneurysm was clamped to improve cerebral and myocardial perfusion. During the 3 minutes of aortic cross-clamping the adherent portion of the left lung was rapidly stripped off the aneurysm and organized thrombus was removed. The lateral ruptured portion of the major sacculation was excised and several lateral clamps were applied to the longitudinal incision which had been made. The aortic clamp was then removed and the defect in the aneurysm, which was 10 cm. long, was repaired with Teflon buttressed sutures. The chest was closed with drainage.

The patient required 28 pints of blood and later surgical evacuation of a haemothorax which had resulted from generalized bleeding. Tracheostomy was necessary and he was ventilated for 1 week. In the second postoperative week he became icteric with the total bilirubin reaching 28 mg. per cent and the blood-urea rising to 300 mg. per cent. He survived without dialysis and was discharged 2 months after operation, with a bilirubin of 1·2 mg. per cent and blood-urea of 20 mg. per cent.

PATHOLOGY OF THE ANEURYSM WALL.—Microscopy showed the aortic media to be replaced by a thick layer of vascular collagen which had neither the lipid encroachment of atherosclerosis nor the round-cell infiltration of syphilis. The elastic tissue was greatly diminished and fragmented. The intima was replaced by organizing mural thrombus. Where the aneurysm abutted on the lung its wall contained clusters of multi-nucleated giant cells. These features are consistent with a diagnosis of middle aortic disease due to an arteritis.

SUBSEQUENT HISTORY.—Two months later a painful abdominal incisional hernia was repaired without complication and a chest film showed no increase in size of the aneurysm. The patient died 3 years later in another country during an operation for aortic excision and graft replacement.

Case 2.—In January, 1967, a 63-year-old white female presented with generalized chest pain of 1 year's duration and a 4-month history of palpitations and faintness precipitated by food. Her blood-pressure was 160/100 mm. Hg. Serological tests for syphilis were negative and an electrocardiogram suggested an old anteroseptal infarction. A plain chest film showed dilatation of the aorta and on barium-swallow examination the oesophagus was deviated to the left by a large uncalcified aneurysm of the descending thoracic aorta. A transfemoral aortogram revealed the entire descending thoracic aorta to be aneurysmal. She was advised to lose weight and to restrict physical activities. One year later her symptoms and chest radiograph were unaltered.

In May, 1968, she gave a 3-month history of left submammary pain which radiated into her left back. There was tenderness in the left epigastrium and the blood-pressure was 170/105 mm. Hg. Marked increase in size of the aneurysm was confirmed by a transfemoral arteriogram. Operation was indicated because of aggravation of symptoms and the recent increase in size of the aneurysm.

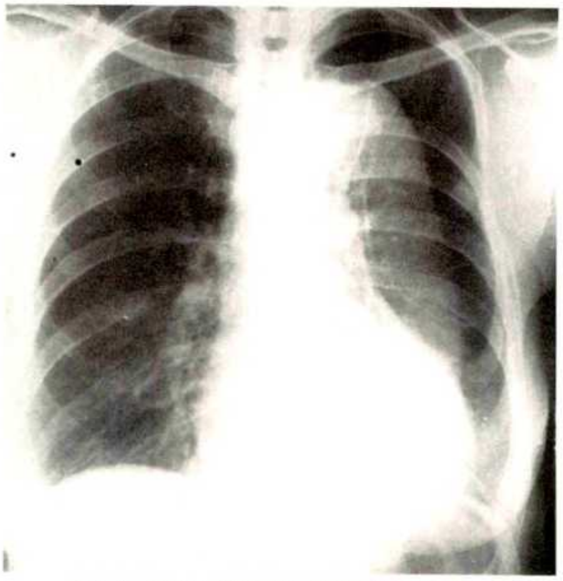

FIG. 2.—*Case* 2. Chest film 1 year after operation.

On 6 June thoracotomy with excision of the left fourth and ninth ribs exposed a fusiform aneurysm of the descending thoracic aorta which was adherent to the lung, oesophagus, and vertebral column. Rupture appeared to be imminent. The size and position of the aneurysm precluded left atrial cannulation. It was therefore decided to insert a Dacron graft end to side to the aorta below and above the aneurysm. The aorta was mobilized below the left subclavian artery and distally at the level of the diaphragm. Following the insertion of this shunt the entire descending thoracic aorta was resected. The aortic cuffs adjacent to the shunt were sutured and the shunt was left to function as the permanent graft. Following operation a left haemothorax developed which required evacuation and a Teflon patch was sutured over a leak in the upper anastomosis. Her course was then uneventful and she was discharged 1 month after operation.

PATHOLOGY OF THE ANEURYSM.—The specimen consisted of a boot-shaped vessel 14 cm. long and dilating in the middle to a diameter of 6 cm. with proximal and distal diameters of 2·5 and 3·5 cm. respectively. The interior was divided into three parts; proximally by an almost transverse diaphragm 3 cm. from the divided end from which the intimal layers had been stripped and folded up and the resulting bare area covered with thrombus. The wall in this region was very thick, white, and fibrous. In the middle third there was a fusiform aneurysm containing mural thrombus and bounded distally by a distinct ridge. Along this ridge the intima showed a slight spiral split 3 cm. long in the floor of which there was thrombus.

Microscopically, the aneurysm wall consisted of collagen interrupted with a network of lymphocytes with total destruction of muscle and almost complete disappearance of elastic tissue. The aneurysm was lined by amorphous thrombotic material undergoing peripheral organization. The picture is one of syphilis.

SUBSEQUENT HISTORY.—The graft is well shown in the chest film taken 1 year after operation (*Fig.* 2). An aortogram was performed in May, 1971 (*Fig.* 3). The patient remains well 5 years after operation and leads an active life. All the peripheral pulses are present apart from a right dorsalis pedis.

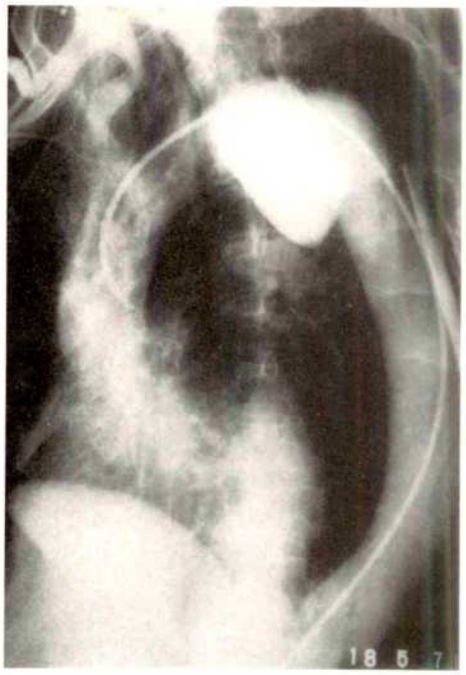

FIG. 3.—*Case* 2. Aortogram 3 years after operation.

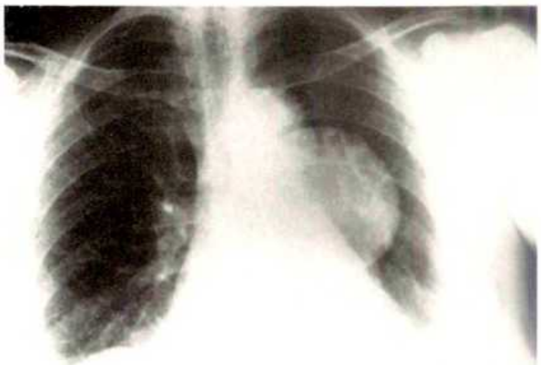

FIG. 4.—*Case* 3. Chest film demonstrating the aneurysm.

Case 3.—An aneurysm of the descending thoracic aorta was diagnosed in a 66-year-old, totally blind, obese white female by mass miniature radiography in February, 1970 (*Fig.* 4). She had congenital syphilis and since 1929 had been blind as a result of luetic keratitis. In 1963 her left eye had been enucleated because of a secondary glaucoma. For 2 weeks prior to radiographic diagnosis of the aortic aneurysm she had complained of a bruised sensation in her left breast and retrosternal pain on walking. Her blood-pressure was 130/90 mm. Hg and all the peripheral pulses were present. Because of her age, obesity, blindness, and lack of knowledge as to the age of the aneurysm surgery was not advised. On 27 Sept., 1970, she developed back pain which 3 days later was so severe that morphine was required and she was admitted as an emergency. She was severely shocked with a systolic blood-pressure of 50 mm. Hg, although both femoral pulses were present. There was a precordial systolic murmur and evidence of bilateral pleural effusions with tracheal deviation to the right (*Fig.* 5). Following blood transfusion she was submitted to operation.

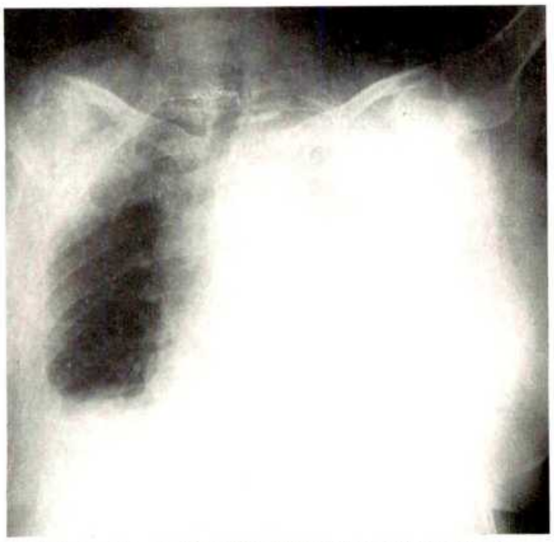

FIG. 5.—*Case* 3. Chest film after rupture of the aneurysm.

Left thoracotomy, excising the fourth and ninth ribs, revealed a large haemothorax but no attempt was made to inspect the aneurysm or the site of rupture. A massive haematoma in the mediastinum had probably limited further leakage. The aorta was mobilized just distal to the left subclavian artery so that any sudden additional haemorrhage could be controlled. The aorta at the level of the diaphragm was treated in a similar manner. A 22-mm.-wide Dacron graft was sutured end to side to the aorta and above the aneurysm, the superior anastomosis being just below the left subclavian artery and the inferior one just below the diaphragm. The aneurysm was then excised between clamps. All the intercostal vessels were thrombosed. The aneurysm was fusiform and atheromatous and on the medial aspect there was a 4-cm. rupture. Her recovery was uneventful and she was discharged home 6 weeks after operation.

PATHOLOGY OF THE ANEURYSM.—The specimen consisted of a retort-shaped aorta up to 7 cm. in diameter at its dilated proximal end, which was thin-walled, obliquely torn, and coated on its inner aspect by laminated mural thrombus. Elsewhere the thin wall appeared somewhat pearly white. The distal 6 cm. of the aneurysm measured less than 3 cm. in diameter and presented an atheromatous inner surface.

Microscopically the original aortic wall was represented by a layer of lipid mush of atheromatous type and a few strands of elastic tissue. Clusters of lymphocytes were seen in the adventitia. This picture is typical of an atherosclerotic aneurysm.

SUBSEQUENT HISTORY.—An aortogram was performed in May, 1971 (*Fig.* 6). The patient remains asymptomatic 2½ years later and leads an active social and domestic life. All the peripheral pulses are present.

OPERATIVE TECHNIQUE OF THE TEMPORARY TO PERMANENT SHUNT GRAFT

Because of its successful application in 2 cases it is perhaps of use to describe the operative details.

1. The patient is placed as for a standard left posterolateral thoracotomy. One long skin incision is made and with adequate retraction the fourth and ninth ribs are removed.

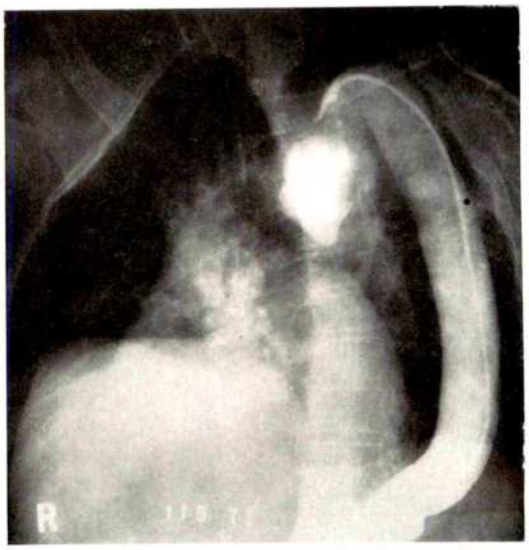

FIG. 6.—*Case* 3. Aortogram 8 months after operation.

2. The exposure is such that the subclavian artery and the aorta above the aneurysm may be mobilized and taped, as may the aorta below the aneurysm, usually at the level of the diaphragm. The aneurysm itself is undisturbed.

3. A Dacron graft of suitable dimension is then sutured end to side to the aorta distal to the aneurysm, employing a Satinsky clamp to occlude the aorta partially (*Fig.* 7). The clamp is then removed and blood is allowed to fill the graft to a convenient level where it is clamped.

4. The graft is then brought up lateral to the aneurysm and sutured to the aorta above the aneurysm in a manner similar to that in which the distal anastomosis was effected (*Fig.* 8).

5. The upper Satinsky clamp is removed and provided that haemostasis is adequate and the graft functioning well the aortic aneurysm, which has not yet been disturbed, is removed after the application of clamps at convenient levels. Each aortic cuff is then oversewn, inevitably producing a small cul-de-sac (*Figs.* 9, 10, 11).

6. The chest is closed in a routine manner after further checking haemostasis and graft function.

DISCUSSION

It is only within the past 20 years that the treatment of aortic aneurysms by resection and graft replacement has been made possible by advances in surgical and anaesthetic techniques and the development of surgical materials. It is not, however, always possible to resect the entire aneurysm, and partial aneurysmectomy in which a portion of the aneurysm wall is excised and aneurysmorrhaphy performed with sutures has been applied to an intact thoracic aortic aneurysm (Cooley and De Bakey, 1955). It appears that this technique has not been described in the treatment of ruptured aneurysms. This method was applied to the first case of the present series. The technique of temporary to permanent shunt successfully employed in *Cases* 2 and 3 could not be used in this instance because of gross constriction of the aorta at the level of the diaphragm and below. *Case* 1 suffered from Sen's disease or the middle aortic syndrome, which is due to a non-specific allergic panarteritis of a segmental nature involving the middle part of the aorta and characterized by irregular constrictions and dilatations (Sen, Kinare, Engineer, and Parulkar, 1963). During the 3-minute period of aortic cross-clamping the aneurysm was partially excised and side-clamps were placed over the defect. The aortic cross-clamp was then removed and the aneurysm was repaired with Teflon-buttressed sutures. This simple procedure undoubtedly saved the life of a patient who was a poor operative risk. A more extensive procedure would have caused his death, which occurred 3 years later during further aortic surgery.

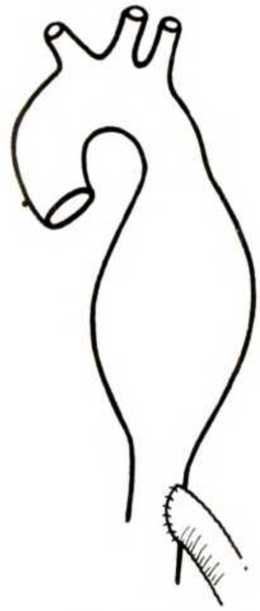

FIG. 7.—The graft is sutured to the aorta distal to the aneurysm.

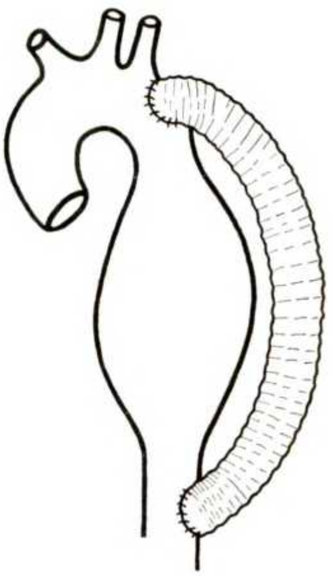

FIG. 8.—The graft in situ prior to excision of the aneurysm.

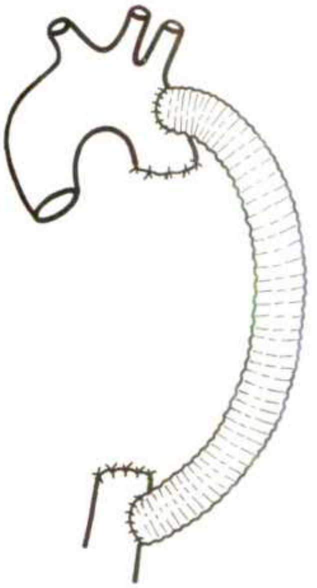

FIG. 9.—Graft with aortic cuffs which are oversewn.

The first successful removal of an aneurysm of the descending thoracic aorta and homograft replacement was performed by De Bakey in 1951 (De Bakey and Cooley, 1953). Natural materials do not form satisfactory grafts and of the many synthetic materials which have been used, the crimped Dacron tube has produced the least number of complications (De Bakey and others, 1958; Crawford, De Bakey, and Cooley, 1958; Nagel and Williams, 1966).

Prior to excision the aorta is cross-clamped above and below the aneurysm. The haemodynamic disturbances thus produced are the proximal deleterious effects on the heart and brain and distal ischaemia, especially of the spinal cord and kidneys (Adams and van Geertruyden, 1956). The effect of clamping or removal of the descending thoracic aorta on the viability of the spinal cord depends on anatomical pattern and segmental distribution of spinal arteries and the development of a collateral circulation following previous obstruction to intercostal vessels associated with disease (Cooley and De Bakey, 1955; Crawford, Fenstermacher, Richardson, and Sandiford, 1970). Attempts to reduce the effect of ischaemia led to the employment of general body hypothermia and local spinal cooling (Beattie, Adovasio, Keshishian, and Blades, 1953; Hardin, Reisman, and Dimond, 1954; Pontius, Brockman, Hardy, Cooley, and De Bakey, 1954; Cooley and De Bakey, 1955; Ellis, Kirklin, and Bruwer, 1958). These techniques were abandoned in favour of methods whereby blood is supplied to the aorta distal to the aneurysm by means of a shunt (De Bakey, Creech, and Morris, 1956). Intraluminal shunts have a limited application in the treatment of aneurysms of the descending thoracic aorta (Lam and Aram, 1951; Crawford, De Bakey, and Blaisdell, 1961; Keon and Trimble, 1968). External shunts detour the aneurysm and either depend on proximal blood-pressure or the assistance of a pump to deliver blood to the distal aorta. Pump-assisted shunts include subclavian-aortic, cardiopulmonary, and the more common left atriofemoral by-pass (De Bakey and others, 1958). The last method failed in *Case* 1 of this series and was technically impossible in *Cases* 2 and 3.

The use of a shunt from the left ventricle to the descending thoracic aorta (Molloy, 1970) is of value in traumatic rupture of the thoracic aorta as this injury usually occurs in a young patient with good ventricular function and a healthy aorta. The technique has a limited application in patients with arteriosclerosis and poor cardiac reserve and would not have been technically possible in the cases described here.

Other external shunts without mechanical assistance convey blood to the distal aorta from the proximal aorta (Chamberlain, Klopstock, Parnasa, Grant, and Cincotti. 1956) or the left subclavian artery (Nagel and Williams, 1966; Kahn, Vathayanon, and Sloan, 1968).

The shunt may be removed after the aneurysm has been excised and a graft then inserted, or it may be left in situ and thereafter function as the graft. Mahorner and Spencer (1954) employed this technique experimentally in 1952 when they by-passed the canine descending thoracic aorta with an homologous arterial shunt which served as the definitive graft after the by-passed segment of the aorta had been removed. There were no neurological complications despite a 50 per cent occlusion of the aortic lumen when the anastomoses were made. This method was first used successfully in 1952 in a patient who had an aneurysm which involved the innominate artery, the first part of the right subclavian artery, and the origin of the right common carotid artery. Because of dense adhesions the posterior surface of the aneurysm was not dissected. A frozen arterial graft was sutured end to side to the base of the innominate artery (below the aneurysm) and to the common carotid artery (above the aneurysm), using clamps to occlude the blood-flow partially during the formation of the anastomoses. The innominate and carotid ends of the aneurysm were then ligated and the shunt was left in situ to function as the permanent graft. About 7 months later re-exploration was indicated because of increasing size of the aneurysm. The pulsating graft had rotated anteriorly over the aneurysm which was then excised. It was observed that the graft was then too long, as it did not have to course across the surface of the aneurysm, although this redundancy caused no ill effects.

Satinsky, Neptune, and Alai (1955) experimentally replaced an aneurysm of the aortic arch with the aid of a homograft vessel shunt which later served as the graft. Bahnson (1956) utilized this technique when resecting an aneurysm of the aortic arch. He also commented on the redundant length of graft but noted that it caused no embarrassment to the patient. Ellison, Cope, and Moretz (1960) employed a shunt of Ivalon sponge which later served as the permanent graft following the resection of descending thoracic aortic aneurysms in 2 patients. They stressed the shorter operating time which is especially important in patients who have other serious organic disease. Bradham and Buxton (1963) used a Teflon shunt to convey blood from the aortic arch to the right common carotid artery when excising a syphilitic aneurysm involving the proximal aortic arch and proximal two-thirds of the innominate artery. The innominate artery was then implanted into a more proximal site in the arch and the Teflon shunt which was functioning well was left in situ.

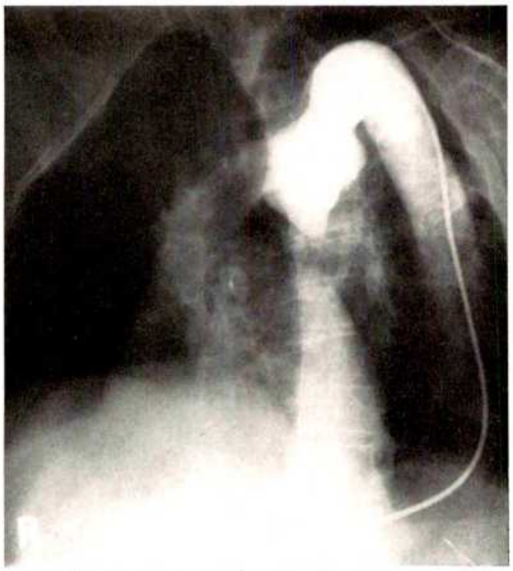

FIG. 10.—*Case* 3. Aortogram demonstrating the upper cul-de-sac.

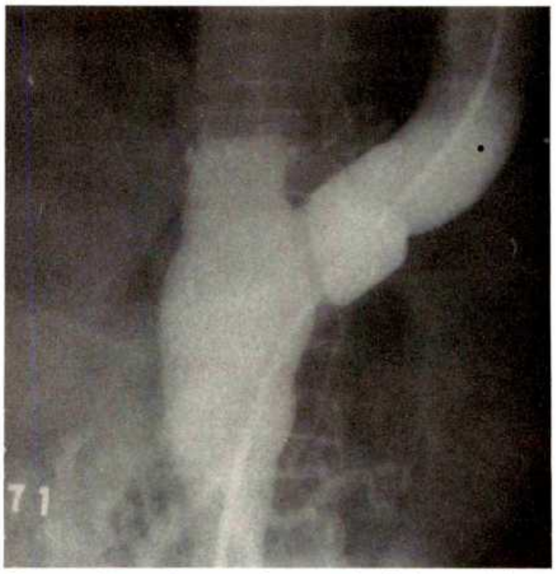

FIG. 11.—*Case* 3. Aortogram demonstrating the lower cul-de-sac.

The development of the crimped Dacron tube allowed this principle to be applied much more readily (De Bakey and others, 1958; De Bakey, 1959). The technique has the disadvantage of leaving an aortic cul-de-sac adjacent to each anastomosis (*Figs.* 9, 10, 11) and, as yet unrecorded, there is the possibility of cul-de-sac disruption, aneurysm formation, or the development of thrombus within a cul-de-sac. The redundant length of the graft appears to cause no inconvenience.

With ruptured aneurysms pump-assisted by-pass is not always possible as the aneurysm is large and prevents access to the left atrium. Crawford and others (1970) reported a series of cases of thoracic aortic resection and replacement with a graft in which a by-pass was not employed. An occluding aortic cross-clamp was placed above and below the aneurysm which was excised and a graft inserted. The series included 2 cases of ruptured aneurysm of the descending thoracic aorta. Although the aortic occlusion time was less than 30 minutes in 70 per cent of the cases it is significant that the occlusion times for the ruptured cases (46 and 64 minutes) were the longest of the series. These patients were already severely shocked prior to operation and any further reduction of the blood-flow to vital organs was therefore critical. Both cases died; one of cerebral insufficiency and the other with paraplegia and pulmonary emboli (*Table I*).

Encouraged by the success of partial aneurysmectomy and the use of a temporary to permanent shunt graft technique it is suggested that these simple procedures have a place in the management of ruptured aneurysms of the descending thoracic aorta. The techniques can be used adjunctively. If during the insertion of the by-pass graft further leakage occurs from the aneurysm, partial aneurysmectomy or merely the application of lateral clamps may be carried out before the insertion of the graft. The methods that we have used have the advantages of simplicity, speed, the avoidance of anticoagulants, and the minimal interference with aortic flow.

1. *Simplicity*: The technique does not involve the use of complicated equipment or the highly trained personnel required for extracorporeal perfusion methods which are available in a thoracic surgical centre. Provided that the surgeon is competent in thoracic and vascular techniques the procedure may be performed in most hospitals.
2. *Speed*: Because of its simplicity the technique results in a reduced operating time.
3. *The avoidance of anticoagulants*: In a patient who has already suffered a severe haemorrhage the avoidance of anticoagulation, which is necessary when a pump is used, considerably reduces haemorrhage at operation.
4. *Minimal interference with aortic flow*: The aorta above and below the aneurysm is only partially occluded during the formation of the graft–aorta anastomoses. The aneurysm is undisturbed until the graft is in place.

Acknowledgements.—Our thanks are due to Professor A. D. Morgan for reporting on the pathological specimens, Dr. B. Strickland for radiological investigations, the Department of Medical Photography and Illustration, Westminster Medical School, for the illustrations, and to Mrs. Goodwynn for secretarial assistance.

ABO BLOOD GROUPS IN OCCLUSIVE AND ECTATIC ARTERIAL DISEASE

By TOM MORRIS and JOHN BOUHOUTSOS

DEPARTMENTS OF SURGERY, ROYAL POSTGRADUATE MEDICAL SCHOOL AND CHELMSFORD AND ESSEX HOSPITAL

SUMMARY

A study of 864 patients with occlusive disease and 246 with ectatic disease was made with reference to their ABO blood groups. The results confirmed the findings of other workers that occlusive disease and myocardial infarction occur more commonly in group-A individuals and that blood group O seems to confer some immunity to occlusive disease. There was also a probable correlation between group A and ectatic disease, but belonging to group O did not seem to confer any protection in this disease. It was also found that the incidence of myocardial infarction was much lower in ectatic disease than in occlusive disease. It is suggested that ectatic disease and occlusive disease are two distinct entities.

THE incidence of the ABO blood groups in many different diseases has been studied for some years and there seems to be a relationship between certain diseases and particular blood groups. For instance, gastric cancer and pernicious anaemia are associated with blood group A, and duodenal ulcer with group O. More recent work suggests that blood groups may also have some influence on arterial diseases. Kingsbury (1971) found a convincing preponderance of blood group A over O in a large number of patients with occlusive arteriosclerosis, and Marcus (1969), in a review of the ABO system, mentioned that myocardial infarction is reported to be more common in group-A subjects. Because of this we decided to study the blood groups in patients with occlusive arterial disease and ectatic disease.

Ectatic disease is characterized by aneurysmal dilatation of arteries and in its extreme form results in localized aneurysms, particularly in the abdominal aorta and the popliteal arteries. These patients rarely have arterial occlusions unless an aneurysm has thrombosed or thrown off emboli.

MATERIAL AND METHODS

The case notes of 1110 non-diabetic white patients treated at Hammersmith and Chelmsford Hospitals since 1958 were reviewed. There were 864 males with occlusive arteriosclerosis, and 246 patients with ectatic disease, of whom 218 were male and 28 female. The patients with ectatic disease had an abdominal aortic aneurysm, a popliteal aneurysm, or both, without arteriosclerotic stenosis of any lower limb vessel; 208 patients had abdominal aortic aneurysm, with or without popliteal aneurysms, and 38 had popliteal aneurysms. Patients with iliac or femoral aneurysms alone were not included in this study, for these aneurysms commonly occur in occlusive disease and we believe that they are often post-stenotic dilatations. For the same reason patients who had an aortic aneurysm together with atherosclerotic stricture were excluded. There were 20 patients with popliteal aneurysms whose blood group had not been recorded and these were also excluded.

The blood group in each case was noted together with any history of myocardial infarction proved by investigation in hospital. The results for the ectatic and occlusive groups were compared with each other and the normal population, using the χ^2 test.

RESULTS

Table I shows the relative frequency of the ABO blood groups among 864 patients with occlusive atherosclerosis and 246 patients with ectatic disease, together with the incidence in the general population. Of the patients with occlusive disease, 47·1 per cent were group A, a higher incidence than would be expected to occur by chance ($\chi^2 = 13{\cdot}313$, $P < 0{\cdot}001$, 1 d.f.), and 37·2 per cent were group O, which is a lower incidence than would be expected to occur by chance ($\chi^2 = 33{\cdot}56$, $P < 0{\cdot}001$, 1 d.f.). Of the patients with ectatic disease, 48·6 per cent were group A and this high incidence is significant ($\chi^2 = 4{\cdot}938$, $0{\cdot}05 > P > 0{\cdot}01$), while the incidence of group O was lower than that in the general population but not significantly so ($\chi^2 = 2{\cdot}204$).

Table II shows the incidence of myocardial infarction related to blood group of 246 patients with ectatic disease and 864 with occlusive disease. There was a large proportion of patients with myocardial infarction among those with occlusive disease compared with those with ectatic disease and this difference was highly significant ($\chi^2 = 88{\cdot}4$, $P < 0{\cdot}001$). The number of patients with myocardial infarction in each blood group was proportional to the total number of patients in that group and the proportions did not differ statistically between one group and another.

DISCUSSION

There are similarities between occlusive and ectatic arterial disease but there are also some differences. The first similarity is the fact that atheromatous plaques, although perhaps not as common in ectatic disease as in occlusive disease, do occur in both. One encounters large calcified plaques in aneurysms, particularly in the aorta and iliac arteries. The second similarity is that aneurysms occur in conjunction with occlusive disease, most commonly in the common femoral artery and the aorto-iliac segment. However, these aneurysms are probably post-stenotic dilatations, for they are always localized, occur distal to a stricture, and can be treated satisfactorily by relieving the stricture, reducing the aneurysm to a normal calibre, and suturing the vessel (Hardy and

Eadie, 1972). The aortic ones are small and do not usually rupture (Bouhoutsos, 1972).

The known differences between occlusive and ectatic disease are more striking than the similarities. First, in ectatic disease all the arteries are of wide bore even when there is no obvious aneurysm, whereas in occlusive disease the vessels are narrow and any aneurysm is very localized. Secondly, unless an aneurysm has thrombosed or thrown off emboli patients with ectatic disease have good pulses and do not usually claudicate. Thirdly, at operation the wide-bore arteries in ectatic disease feel soft and although their walls are quite thick they seem structureless and sutures cut out very easily, compared with normal or even rebored atheromatous arteries. They must be considerably weaker than the arteries in occlusive disease, for the latter can be rebored to leave only a tissue-paper-thick wall without becoming aneurysmal. Fourthly, we have shown (Morris and Bouhoutsos, 1973) in our series of patients that those with ectatic disease are more commonly Rhesus negative than the general population and patients with occlusive disease are more commonly Rhesus positive.

Table I.—INCIDENCE AND PERCENTAGE FREQUENCY OF THE ABO BLOOD GROUPS AMONG 864 CASES OF OCCLUSIVE DISEASE AND 246 CASES OF ECTATIC DISEASE COMPARED WITH THE PERCENTAGE INCIDENCE IN THE GENERAL POPULATION

BLOOD GROUP	GENERAL POPULATION (per cent)	OCCLUSIVE DISEASE		ECTATIC DISEASE	
		No.	Per cent	No.	Per cent
A	41	407	47·1	118	48·6
O	47	321	37·2	104	43·3
B	9	96	11·1	20	6·7
AB	3	40	4·6	4	1·4

Because of these differences between occlusive and ectatic disease we undertook this study to see if they differed in relation to ABO blood groups and myocardial infarction. Our results confirm the findings of Kingsbury (1971) that blood group A tends to predispose to occlusive arterial disease whereas group O seems to confer some degree of immunity to it. We found a probable relationship between group A and ectatic disease, but this was not definite and the incidence of group O among the patients with ectatic disease did not differ significantly from the incidence of group O in the general population. Kingsbury (1971) also found no change in the A : O ratio in patients with aneurysms. These findings, together with the highly significant difference in the incidence of myocardial infarction between the groups with occlusive and ectatic disease, are further evidence in favour of the hypothesis that these are two different disease entities which share some characteristics rather than two manifestations of a single disease.

Table II.—INCIDENCE OF MYOCARDIAL INFARCTION AMONG 246 CASES OF ECTATIC DISEASE AND 864 CASES OF OCCLUSIVE DISEASE RELATED TO ABO BLOOD GROUPS

BLOOD GROUP	ECTATIC DISEASE			OCCLUSIVE DISEASE		
	Total No.	*Myocardial Infarction*		*Total No.*	*Myocardial Infarction*	
		No.	Per cent		No.	Per cent

A REVIEW OF 174 PATIENTS WITH ARTERIAL EMBOLISM*

By W. A. L. MacGOWAN and R. MOONEERAM
SURGICAL PROFESSORIAL UNIT, ST. LAURENCE'S HOSPITAL, DUBLIN

SUMMARY

Experience of 174 patients suffering from arterial embolism is recorded. One hundred and fifty cases occurred in the lower limb and 24 in the upper limb. Embolectomy was performed in 119 patients. The overall limb salvage rate was 62 per cent and the hospital mortality was 27 per cent. Amputation was performed in 13 per cent of the patients in this series. Operative techniques and management are discussed. Delay in diagnosis and effective surgical treatment appears to be a major factor influencing the end-result.

PRESENT SERIES

Between 1959 and 1972, 174 patients were admitted to the Surgical Professorial Unit of St. Laurence's Hospital, Dublin, with arterial embolism. The age range was 32–88 years, most patients being aged between 60 and 70 years. The male : female ratio was 2 : 1. The upper limb was affected in 24 patients and the lower limb in 150. Two patients sustained a second femoral embolus after an interval of 2–3 years. Both of these patients had been on oral anticoagulant therapy after the first operation, but this had been discontinued by a physician some 2 weeks prior to readmission. A second embolectomy was successfully performed and both patients were re-established on oral anticoagulant therapy.

DIAGNOSIS

In a known cardiac patient, particularly with atrial fibrillation, a sudden vascular incident in a limb or limbs is suggestive of peripheral arterial embolism. Pratt's points (Pratt, 1949) are still useful guides to diagnosis: the 'pistol-shot' onset of pain, pallor, paraesthesia or anaesthesia, paralysis, and pulselessness in a limb 'perished' with cold are still simple pointers to the diagnosis of this common condition. Acute thrombosis in a diseased vessel can be confused with an acute embolism and sometimes arteriography may be necessary to determine the diagnosis. With peripheral embolism there is a sharp 'cut-off' and a concave defect in the contrast caused by the embolus. Collateral circulation is poor or absent. In acute thrombosis these features are usually absent and a collateral circulation is evident (*Figs.* 1, 2).

Arteriography.—Arteriography is only used as an aid to diagnosis; for instance, when there is difficulty in distinguishing thrombosis from embolism. It may also be used for investigating the source of the embolism such as an aneurysm. However, it is very useful as an intra-operative investigation and is used routinely for this purpose in this unit (*see below*).

ORIGIN OF THE EMBOLUS

The origin of the embolus (*Table I*) was determined by chest radiography, arteriography, operative findings, and autopsy findings where appropriate in 59 of the 174 patients. The commonest site of origin was an atheromatous aorta or aneurysm of the aorta or its main branches. Thrombus in the left atrium associated with mitral valve disease was considered to be responsible for peripheral embolism in 17 patients. Mural thrombus associated with infarction of the left ventricle was found in 10 patients. In 2 patients the embolus originated from a subclavian aneurysm associated with a cervical rib. In 115 patients the cause was undetermined but in 107 patients (two-thirds) atrial fibrillation was present.

SITE OF EMBOLISM

Although in most instances there were multiple emboli in one or both limbs, the primary site of occlusion appeared to be, in the case of the lower limb (*Table II*), the aorta in 8, iliac artery 4, femoral artery 102, and popliteal artery 36. The femoral artery, therefore, appears to be the commonest impaction site for embolism in the lower limb but there was often a further smaller embolus impacted in the popliteal artery as well. This was not an uncommon combination. In the case of the upper limb (*Table III*) the subclavian artery was the site of impaction in 2 patients, the axillary artery 3, the brachial artery 17, and the radial artery 2. In this series the brachial artery, therefore, appeared to be the commonest site of impaction for an embolus in the upper limb.

TREATMENT

The treatment will depend mainly on the age and general condition of the patient, the state of the limb (whether it is salvageable or irreversibly damaged), and the time interval between the onset of symptoms and admission to a vascular unit. In general, operative treatment is preferred. The patient must be generally fit for surgical treatment and the limb must be salvageable, otherwise there is no definite time limit. If there are irreversible changes in the limbs such as skin staining, rigidity of the muscles, or obvious gangrene then it is best to proceed with amputation. The treatment of choice, however, is embolectomy performed with the aid of a balloon catheter (Fogarty, Cranley, Krause, Strasser, and Hafner, 1963). This has made the operation a simple procedure which can be performed if necessary under a local anaesthetic. Heparin, 12,000 units intravenously, is given immediately the condition is diagnosed to prevent propagation of thrombus (proximal and distal to the embolus) and deterioration in the limb prior to surgical treatment. Heparin is also used intra-operatively in saline (5000 I.U. per 500 ml.) to flush the vessels. It is occasionally used as an intravenous infusion postoperatively in a patient prone to further clotting incidents, particularly when a late embolectomy has been performed. After a late embolectomy the vessels are often still roughened by adherent mural thrombus and re-thrombosis is a common complication. Heparin therapy in the early postoperative period may be of value under these circumstances in reducing postoperative re-thrombosis, although haemorrhage from the operative wound is a hazard. Closed-wound drainage is mandatory when anticoagulation is used. All patients are established on oral anticoagulant therapy after operation and this is continued on a permanent basis unless the causative lesion is corrected; if not there is a definite danger of further embolism.

---

* Based on a paper read at the Annual Meeting of the Vascular Surgical Society of Great Britain and Ireland in Dundee, October, 1972.

Table II.—SITE OF THE EMBOLUS IN 150 CASES OF LOWER-LIMB EMBOLISM

Site of Embolus	*No. of Cases*
Aorta	8
Iliac artery	4
Femoral artery	102
Popliteal artery	36

Operative Technique.—The procedure is performed preferably under a general anaesthetic, although occasionally with a local anaesthetic. In the lower limb the approach is usually made through the common femoral artery. Both arteries should be exposed if an iliac or aortic embolism is suspected because clot can be pushed up by the catheter and then find its way down the contralateral limb so that operative removal is required. To prevent distal embolization to the contralateral limb it is a wise precaution to occlude the opposite femoral artery temporarily before passage of the catheter.

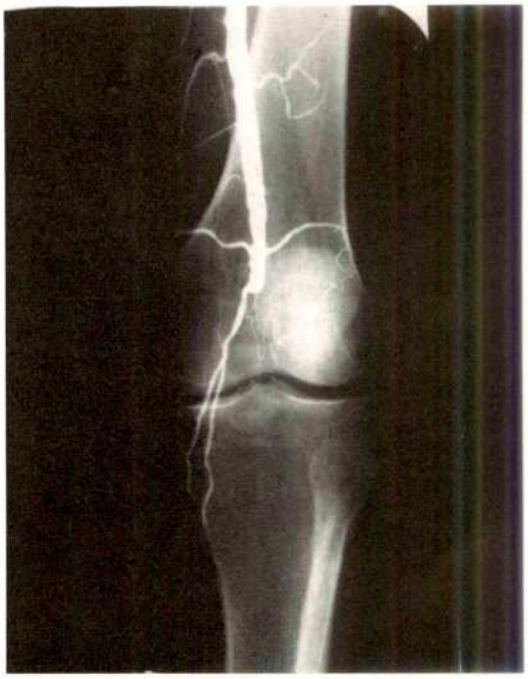

FIG. 2.—Arteriogram showing an acute occlusion of the popliteal artery caused by atherosclerosis. Note the tapered appearance of the vessel and the irregularity of its wall. A collateral circulation is evident.

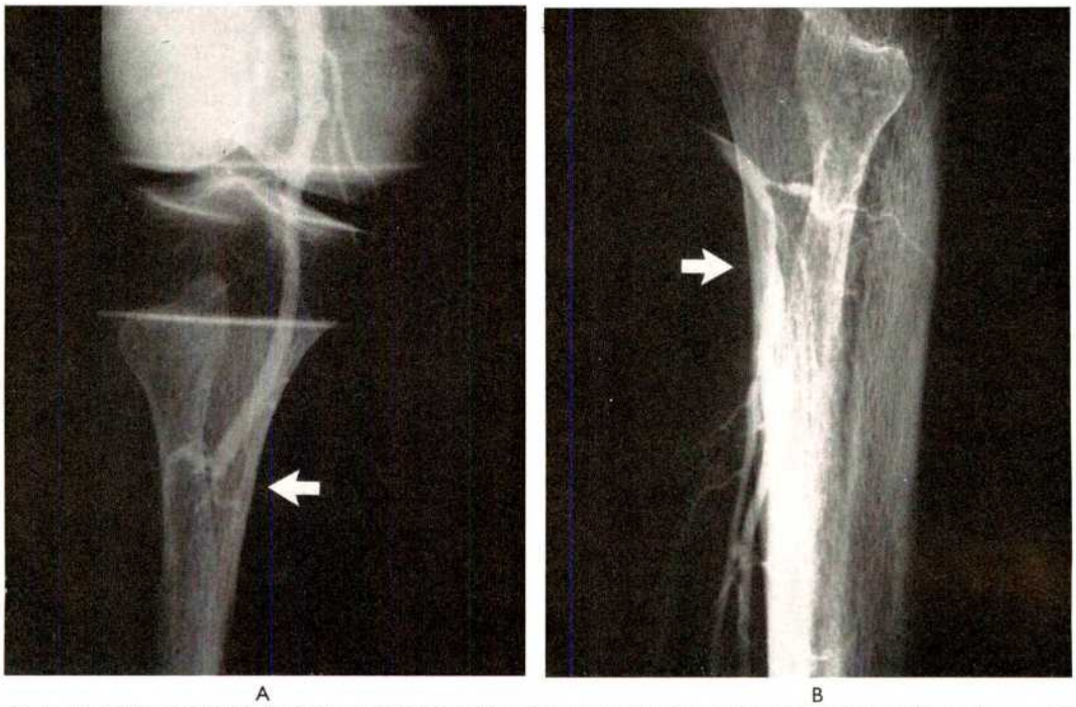
Table III.—SITE OF THE EMBOLUS IN 24 CASES OF UPPER-LIMB EMBOLISM

Site of Embolus	*No. of Cases*
Subclavian artery	2
Axillary artery	3
Brachial artery	17
Radial artery	2

In the upper limb embolectomy is usually performed through a small transverse incision in the brachial artery. Occasionally the more difficult exposure of the subclavian or axillary vessels may be necessary. A Fogarty catheter (available sizes 3–7F) is passed gently upwards, avoiding trauma to the intima. The correct inflation pressure advised by the manufacturer should be used and over-distension avoided. During withdrawal if resistance is met the balloon should be deflated, the object being to have a snug fit between balloon and vessel wall. A Foley urinary catheter (size 18F) can be a very useful instrument for removal of iliac and aortic emboli (MacGowan, 1965). The catheter's position above the embolus is apparent when blood gushes from the central lumen of the Foley catheter. The catheter is clamped, inflated, and withdrawn. It is less rigid than the Fogarty catheter and thus damage to the iliac artery and aorta may be avoided. If the proximal obstruction cannot be cleared or the catheter fails to pass, then an intra-operative angiogram is called for and will demonstrate the causative lesion, e.g., an acute thrombosis in a stenosed vessel. Under these circumstances the vessel is exposed and an appropriate reconstruction performed. The proximal obstruction must, therefore, be cleared first and a good flow restored. The vessel is then secured on the proximal side of the arteriotomy and attention is now paid to the distal arterial tree. A Fogarty catheter of smaller



A B

FIG. 3.—A, Anteroposterior intra-operative arteriogram performed by direct injection of contrast into the open femoral artery. Note residual clot occluding the posterior tibial artery (arrowed). Passage of a small Fogarty catheter (size 3F) cleared this obstruction as arrowed in the lateral radiograph (B).

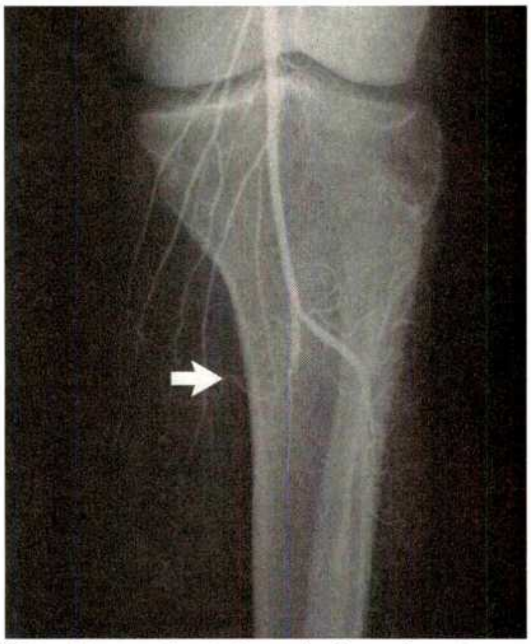


FIG. 4.—Intra-operative arteriogram showing persistent obstruction of the posterior tibial artery by residual clot.

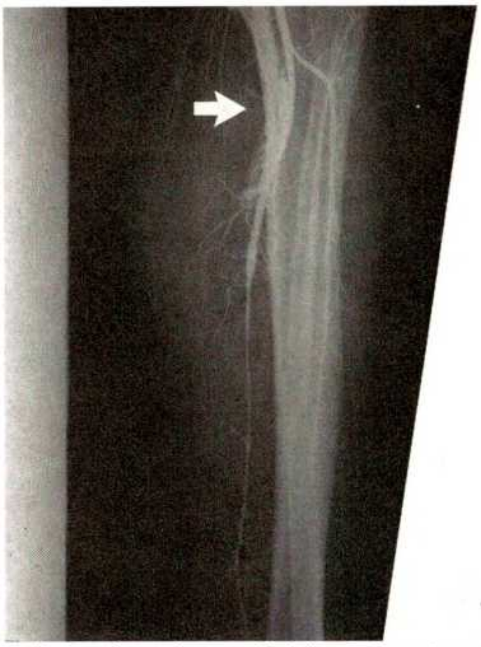

FIG. 5.—Over-zealous use of a balloon catheter clears the clot at the expense of the artery. Over-distension of the balloon has ruptured the vessel and contrast has escaped into the tissues. This vessel must now be repaired.

size is passed distally again with care to avoid intimal damage and vessel penetration. Retrograde flushing (Olwin, Dye, and Julian, 1953) through the anterior tibial or radial artery combined with 'milking' of the limb are useful procedures to augment the balloon-catheter extraction. Intra-operative arteriograms are now performed on the open femoral or brachial vessel by a single injection of contrast through a cannula or catheter. Before closing the arteriotomy the operator should be satisfied that the distal arterial tree has been cleared of clot as far as is possible. It is imperative to remove the distal clot and this applies particularly to the popliteal artery and its three main branches. If necessary the popliteal artery is exposed and the clot removed at arteriotomy. Reliance on backflow is unsatisfactory and unless the distal vessels can be cleared the chances of saving the limb are considerably reduced (*Figs.* 3). Intra-operative arteriography may also demonstrate unsuspected damage to the vessels by the balloon catheter (*Figs.* 4, 5) (Mavor, Walker, and Dahl, 1972; Mavor, Walker, Dahl, and Pegg, 1972). Closed drainage of the wound is usually employed to avoid haematoma formation.

Conservative Treatment.—Conservative treatment consists of the continuous intravenous infusion of heparin followed by oral anticoagulants. It is usually reserved for the elderly or infirm who are unfit for operation, or for a limb which is obviously improving after the initial embolus. Such treatment may prevent deterioration by further thrombosis or embolism. Amputation is reserved for the limb which is irretrievably damaged and frank gangrene. It is thus required when embolectomy fails to salvage a limb.

Table IV.—COMPARISON OF CONSERVATIVE AND SURGICAL TREATMENT

TREATMENT	UPPER LIMB		LOWER LIMB	
	No. of Cases	No. of Limbs salvaged	No. of Cases	No. of Limbs salvaged
Embolectomy	20	20	99	78
Conservative	4	4	51	7

RESULTS OF TREATMENT

On comparing conservative and operative treatment (*Table IV*) for the upper limb all the limbs were salvaged. The risk to the limb in the case of the upper limb is less than with the leg. Nevertheless loss of upper limbs can occur and is a catastrophe compared with the excellent prostheses now available to replace the amputated lower limb. Twenty embolectomies were performed for upper-limb emboli which we believe would, if treated conservatively, have led to loss of a limb or at least a severely damaged one. Embolectomy of the upper limb-vessels is usually necessary, particularly if the limb remains cold and discoloured some hours after the onset of the embolism. Conservative management is justifiable for the poor-risk elderly patient whose limb is obviously improving.

In the lower limb conservative treatment yields poor results and operative treatment is necessary in the vast majority of patients if the limb is to be salvaged (*Table IV*).

The overall results are reviewed in *Table V* and it is to be noticed that the number of admissions has increased over the years of the survey. The number of patients having operative treatment has also increased, while the hospital mortality has been reduced from somewhere in the region of 50 per cent in the period 1959–65 to 7 per cent in 1972. This is because of better selection, anaesthetic care, and medical care, and the speed and effectiveness with which the operation can now be performed using the Fogarty catheter. The amputation rate is 13 per cent overall and the overall limb salvage rate is 62 per cent, which again has improved over the years from 53 per cent in 1959–65 to 82 per cent in 1972. The number of hospital deaths (*Table VI*) was 48 and most of those were caused by cardiac failure or pneumonia. Many of the so-called 'pneumonic' deaths were probably unsuspected pulmonary infarction which is so common after peripheral embolism. The high mortality is indicative of the serious cardiovascular and respiratory disease from which these patients suffer. Embolism is an incident in these diseases; an incident, however, which can have fatal consequences for many patients.

Table V.—SUMMARY OF THE RESULTS OF TREATMENT IN 174 PATIENTS WITH PERIPHERAL ARTERIAL EMBOLISM, 1959–72

YEAR	NO. OF CASES	OPERATION	HOSPITAL MORTALITY		AMPUTATION	LIMBS SALVAGED	
			No.	Per cent		No.	Per cent
1959–65	32	22	16	50	3	17	53
1966	16	7	6	37	2	8	50
1967	4	2	1	25	2	2	50
1968	18	9	5	27	2	11	61
1969	27	18	8	29	4	15	55
1970	35	25	8	22	4	23	65
1971	14	11	2	14	2	10	71
1972 (Jan.–Aug.)	28	25	2	7	5	23	82
Total	174	119 (68 per cent)	48	27	24 (13 per cent)	109	62

Table VI.—CAUSE OF HOSPITAL DEATHS

Cause of Death	*No. of Cases*
Cardiac failure	18
Pneumonia	11
Myocardial infarction	9
Pulmonary embolism	4
Uraemia	3
Cerebrovascular accident	3

Table VII.—TIME BETWEEN ONSET OF SYMPTOMS AND EFFECTIVE TREATMENT IN LOWER-LIMB EMBOLISM

DELAY	NO. OF CASES	PER CENT	EMBOLECTOMY	NO. SALVAGED	FAILURE RATE (per cent)
0–12 hr.	18	12	18	17	5·5
12–24 hr.	38	25	38	35	8
1–2 d.	60	40	49	39	35
2–4 d.	29	19	10	5	82
4–8 d.	19	12	3	1	94
Over 8 d.	10	6	1	1	90

Analysing the delay before effective treatment was instituted (*Table VII*) the average time interval between the occurrence of the embolism and treatment in the upper limb was 12–72 hours, with one exception of 4 days. Obviously the patients presented earlier in the case of the upper limb because the effects are manifested earlier to the patient, relatives, and medical practitioner. In the lower limb (*Table VII*) only 12 per cent of our patients arrived within the first 12 hours of the onset of the embolism, presuming that this coincided with the onset of symptoms. The success rate of embolectomy in this group of patients was 94·5 per cent. The vast majority of patients, however, appeared to arrive in hospital some days after the onset of embolism and it can be clearly seen that the failure rate of embolectomy increases as the delay before effective treatment increases. This is shown graphically in *Fig.* 6; the percentage failure for embolectomy increases to its maximum of nearly 100 per cent following a delay of over 8 days before effective treatment is instituted. Nevertheless, surprisingly, many limbs are salvaged after a considerable delay.

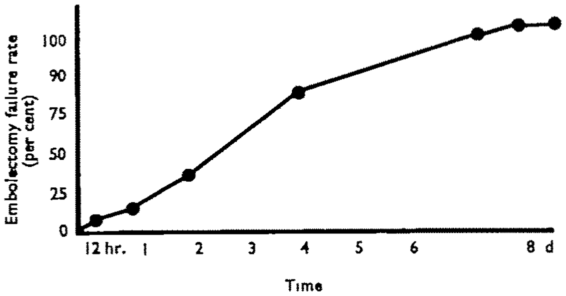

FIG. 6.—Embolectomy failure rate related to the delay before operation.

DISCUSSION

A large series of patients with peripheral arterial emboli, comprising 174 consecutive patients seen over a period of 13 years, has been reviewed. One hundred and nineteen embolectomies were performed and this compares with series of 260 patients reported by Darling, Austen, and Linton (1967) and 80 patients by Martin, King, and Stephenson (1969). In the present series there was commonly a delay of 1–8 days after the onset of symptoms before the patients were admitted for effective treatment. Only 12 per cent of the patients were admitted within 12 hours of the onset of symptoms. This compares with 76 per cent in Darling's series and 41 per cent in Martin's series. It is probable that both of these hospitals were dealing with a local metropolitan area whereas the catchment area of St. Laurence's Hospital is countrywide. Many of the patients were referred from long distances and hence the delay. The overall salvage rate was 62 per cent, but over the past 3 years this has risen to between 70 and 80 per cent. In Darling's series the salvage rate was 91 per cent and in Martin's series 84 per cent. The overall amputation rate in the present series was 13 per cent, in Darling's series it was 9 per cent and in Martin's series 11 per cent. As the delay before effective treatment increases, the amputation rate also increases. The results of embolectomy in this series are, therefore, somewhat less favourable when compared with other published series. This is explained by the late admission for effective surgical treatment caused by the delay in diagnosis and the distances to be travelled to the appropriate specialist hospital. Most of the patients arrived at least 12 hours after the onset of symptoms, the clot having become adherent and propagated thrombosis having caused deterioration in the collateral circulation. The longer the clot is present, the greater is the extent of the thrombosis, the more adherent it becomes, and the more difficult it becomes to remove it, and the less effective its removal (Thompson, Sigler, Raut, Austin, and Patman, 1970; Hamer, 1972).

The overall hospital mortality in our series was 27 per cent but in 1971 it had reduced to 14 per cent and now in 1972 to 7 per cent. In Darling's series it was 29 per cent and in Martin's series 21 per cent.

CONCLUSIONS

On review of this series of 174 patients with arterial embolism the following conclusions were reached:—

1. The diagnosis of peripheral embolism is still made too late. Earlier diagnosis can be made by clinical awareness in susceptible patients and will lead to a higher limb salvage rate.
2. Intravenous heparin should be given immediately diagnosis is made to prevent spreading of thrombosis and further deterioration in the limb.
3. The vast majority of patients will need embolectomy if the limb, either upper or lower, is to be saved.
4. Intra-operative arteriography is mandatory if consistently good results are to be achieved.
5. The balloon-catheter extraction technique has considerably improved operative results and mortality.
6. Long-term anticoagulants are necessary to prevent recurrence unless it is possible to remove the source of the emboli.

Acknowledgements.—I wish to acknowledge the assistance of my colleagues Mr. Gearoid Lynch and Mr. Hyacinth Browne. I am also indebted to Mr. James Mulvanny, A.I.I.P. (Med.), for the radiographs.

Post-prostatectomy EPSIKAPRON® is better than post-prostatectomy bleeding*

This observation has a high degree of clinical significance.

Post-prostatectomy blood loss may be a litre or more[1,2]. Use of EPSIKAPRON can reduce this loss by 80-90%[3,4]. "The control of blood loss has proved to be not only statistically but also clinically significant"[2]. Blood transfusion, which is costly and not without risk, ". . . can be avoided and draining catheters kept patent without difficulty and removed earlier, which makes the post-operative course smoother and shorter"[3].

SURGICAL RESEARCH SOCIETY

A meeting of the Surgical Research Society was held in the University of Bristol on 6 and 7 July, 1973, with Professor L. P. Le Quesne (President of the Surgical Research Society) in the Chair. The following papers were presented:—

1. Arterial Damage by Trackless Lesions in the Spinal Cord made by Focused Ultrasound: H. B. Griffith, B. Brownell, J. B. Bowes, M. Halliwell, and P. N. Wells, Departments of Surgery and Neurosurgery, University of Bristol.

Ultrasound brought to a focus can produce uniform trackless lesions in the nervous system. In the brain white matter is more vulnerable than grey, but the converse has been found in the spinal cord (Lele, 1967). In an experimental study in pigs, mounted to test the practicability of ultrasonic commissurotomy for pelvic pain in man, a series of uniform lesions were made, using a power output of 2 W. for 4 seconds at a frequency of 2 MHz.

It was found that the grey matter is spared selectively and that when the midline branches of the anterior spinal artery are involved in the ultrasonic lesion an obliterative arteritis results. It was also noted that even in the presence of this vascular change, the motor neurons of the anterior horns, which are especially liable to ischaemic or mechanical damage, may not show pathological changes.

It is likely that focused ultrasound at this frequency produces its effects by thermal release, and the rates of blood-flow through grey and white matter may be crucial in determining whether a lesion is produced. The hitherto undescribed arteritis may partly explain why grey-matter damage has been previously seen. There is a good prospect of making a safe selective therapeutic lesion in man.

Lele, P. P. (1967), *Ultrasonics*, **6**, 105.

2. Antidiuretic Hormone Response in Patients undergoing Surgery on High and Conservative Fluid Régimes: C. S. Sinnatamby, M. H. Irving, C. R. W. Edwards, and M. Kitau, Departments of Surgery and Chemical Pathology, St. Bartholomew's Hospital, London.

The view that postoperative water loads should be restricted because of an obligatory antidiuretic hormone (ADH) response is challenged by the intravenous administration of sufficient fluid to compensate for reductions in blood-volume and effective extracellular fluid, both of which act as stimuli to ADH production.

ADH production was studied in two groups of 4 patients by radio-immunoassay of arginine vasopressin production in 24-hour urine samples from the day prior to operation through to the end of the second postoperative day.

Fluid intake was identical in both groups on the day prior to operation. On the day of operation patients in the high fluid-load group received replacement of the estimated blood-loss plus 15 ml. per kg. per hr. of Hartmann's solution. At the end of the operation the patients commenced on a régime of dextrose, 5 per cent, and normal saline at a rate of 4 litres per 24 hours. The second group, on the conservative régime, received replacement of all blood-loss plus 5 ml. per kg. per hr. during the operation and 1·5 litres of fluid per 24 hours from the end of the operation.

Operation caused a marked increase in the arginine vasopressin content of the urine in both groups, the level being unaffected by the fluid load. Patients on a high fluid load excreted significantly more urine on the first and second postoperative days (3851 ± 762; 3269 ± 592) than did patients on the conservative régime (1351 ± 271; 1695 ± 224). The high fluid-load group had lower urine and plasma osmolalities.

It is concluded that although urine output in the immediate postoperative period can be increased by a high fluid intake this is not the result of suppression of the ADH response.

3. The Effect of Cholecystectomy on the Composition of Bile in Gall-stone Patients: D. C. Smith, R. A. McAllister, and C. Mackay, University Department of Surgery, Western Infirmary, Glasgow.

Eleven patients, each with a functioning gall-bladder, admitted for elective cholecystectomy for gall-stones were studied. At operation bile was aspirated from the gall-bladder and the common duct and the stones were retained for analysis. Six months to 2 years later further samples of bile were obtained by duodenal intubation. The concentrations of bile-salt, cholesterol, and phospholipid were estimated and the relative composition of each sample was calculated (Admirand and Small, 1968). Individual bile-salts were estimated using thin-layer chromatography.

Eight patients had cholesterol gall-stones (mean cholesterol content 92 per cent) and 3 had pigment stones (mean cholesterol content 6·8 per cent). The relative composition of the common bile-duct bile at operation in 5 of the 8 patients with cholesterol stones lay outwith the zone of cholesterol solubility. However, on follow-up the relative composition lay within the zone of cholesterol solubility on both occasions. Cholecystectomy produced no significant changes in the individual bile-salts.

Cholecystectomy alters the relative composition of bile in such a way as to render further stone formation less likely.

Admirand, W. H., and Small, D. M. (1968), *J. clin. Invest.*, **47**, 1043.

4. Macrophage Phagocytic Activity in Patients with Breast Cancer: M. Baum, D. Sumner, M. H. Edwards, and P. Smythe, Department of Surgery, King's College Hospital, London.

The monocyte/macrophage system of cells plays a critical role in the host response to cancer (Baum and Fisher, 1972). An indirect method of monitoring the activity of these cells by measuring the clearance of radioactive micro-aggregated albumin by the sinusoidal macrophages of the liver and spleen was first described to the Society by Mackay et al. (1968).

Using this technique the macrophage phagocytic activity (K value) of 47 women with breast cancer was estimated prior to any treatment. The patients were subdivided according to whether the disease was localized to the breast and underlying muscle (T1–4, N0, M0), or whether the cancer had disseminated to the regional nodes or beyond (T1–4, N1 and/or M1). Included in the latter group were patients with occult bone metastases detected by skeletal scintigraphy.

The mean K value of the patients with localized disease was 63, whilst for those with dissemination it was 52. This difference is significant ($\chi^2 = 4{\cdot}584$, $P = 0{\cdot}05$). There appeared to be a linear correlation between tumour size and K value when the disease was localized ($r = 0{\cdot}47$, $P < 0{\cdot}05 > 0{\cdot}02$), but this relationship was lost in patients with dissemination.

These results suggest that as long as the macrophage response of the host to cancer remains intact the disease may remain localized.

5. A Comparison of Methods of Immunological Reconstitution of Immunologically Unresponsive Mice: D. N. H. HAMILTON, C. E. REID, D. G. GILMOUR, and P. R. F. BELL, University Department of Surgery, Western Infirmary, Glasgow.

In human malignancy the establishment and growth of the tumour may be the result of an absent or ineffectual immunological response. Immunotherapy designed to stimulate (Mathé, 1972) or to restore with lymphocytes (Yonemoto and Terasaki, 1972) this possible deficiency in cell-mediated immunity has met with some success.

To study methods of reconstitution CBA mice were rendered unresponsive to 'A' strain grafts by two methods:—

1. *Specific Tolerance*: Induced by neonatal injection of F^1 CBA/A cells.

2. *Non-specific Anergy*: Obtained by adult thymectomy, lethal irradiation, and bone-marrow reconstitution ('B' mice).

The ability of various immunological therapies to reject the graft was studied and showed first, using infusion of lymphocytes, that while 10^7 sensitized cells were required to restore the tolerant mice only 10^5 sensitized cells were required for the 'B' mice; 10^6 normal lymphocytes could restore the 'B' mice but the maximum dose of normal lymphocytes given (10^7) failed to affect the tolerant mice. Young thymus grafts placed under the kidney capsule restored the 'B' mice but did not reconstitute the tolerant animals.

Thus specific tolerance presents a much greater barrier to reconstitution than anergy by a factor of 100, and suggests that the clinical success of immunotherapy may be related to the type of deficiency present.

6. An Assessment of a Simple Test for Gram-negative Endotoxaemia: D. P. FOSSARD and V. V. KAKKAR, Department of Surgery, King's College Hospital Medical School, London.

The diagnosis of endotoxic shock in surgical patients usually depends on obtaining a positive blood-culture, which may take several days. The value of a simple and rapid test which can be used to detect the presence of circulating Gram-negative endotoxins has been assessed. The test is based on the ability of Gram-negative endotoxins to coagulate a protein moiety obtained from the horseshoe crab.

The study was done in two parts. In the first part using 20 experimental animals blood samples were obtained from the portal and systemic circulations before and after bowel resection. It was possible to detect endotoxin in concentrations as low as 10^{-8} μg. per ml. In the second part of the study 12 patients with acute inflammatory abdominal conditions were investigated. Frequent blood samples were withdrawn for blood-culture and endotoxin assay. The endotoxin assay was positive in all except 1 patient. Once the infection was controlled the assay became negative. In 3 patients who had positive blood-cultures the assay also detected the presence of endotoxin.

It is concluded that the endotoxin assay is a simple, rapid, and sensitive method of detecting endotoxaemia and observing the patient's response to treatment. It may also be useful as a screening test for detecting patients who have minor degrees of endotoxaemia prior to surgery.

7. Gall-stone Dissolution *in vitro:* K. E. FARRELL, D. C. SMITH, and C. MACKAY, University Department of Surgery, Western Infirmary, Glasgow.

Retained stones after choledocholithotomy present a surgical problem and their dissolution by means of solutions introduced through an indwelling T-tube is an attractive goal. Cholesterol, the major constituent of gall-stones, is readily dissolved in lipid solvents but these are unphysiological. We have therefore measured the rate of dissolution of gall-stones in physiological solvents.

Gall-stones weighing 40–50 mg. and containing more than 95 per cent cholesterol were placed in 5 per cent bile-salt solutions with and without lecithin. The bile-salts studied were glycine and taurine conjugates of cholic, chenodeoxycholic, and deoxycholic acids. The solutions were sterilized by Millipore filtration, sealed in sterile tubes, and gently agitated in a water-bath at 37° C. The stones were weighed regularly using an aseptic technique.

Stones lost weight rapidly over the first 7 days and more gradually thereafter. To standardize interpretation the dissolution rate for each solvent was expressed as the time required to reduce the stone to half its original weight ($T_{\frac{1}{2}}$) at the dissolution rate occurring during the first 7 days of study. The $T_{\frac{1}{2}}$ was lowest for the glycodeoxycholate and lecithin solution (4 days) and greatest for the taurocholate solution (20 days). Glycine-conjugated dihydroxy bile-salts were the best solvents and all the solvents were improved by the addition of lecithin.

Thus, cholesterol gall-stones comparable in size to common-duct stones can be dissolved *in vitro* at a rate which would be useful in clinical practice.

8. Cervical Lymphovenous Shunt in Intractable Ascites—A Clinical Study: M. M. SEIN (R. Shields), Departments of Surgery, Institute of Medicine, Rangoon, Burma, and University of Liverpool.

Hitherto the surgical treatment of ascites which does not respond to conventional medical treatment has been unsatisfactory. In 8 patients with intractable ascites and advanced hepatic cirrhosis cervical lymphovenous shunt was performed—the thoracic duct in the neck was divided and anastomosed to the lower end of the internal jugular vein.

In 7 patients there was a marked reduction in ascites as demonstrated by a significant fall in the body-weight (mean fall, 13·7 kg.; $P < 0·001$) and decrease in abdominal girth (mean decrease, 41·85 cm.; $P < 0·001$) by the seventh to fourteenth postoperative days.

Immediately after operation the central venous pressure was increased and remained elevated (mean increase 5·4 cm. water; $P < 0·001$) for 7–8 hours to return eventually to preoperative levels. After an initial oliguria there was a massive diuresis with return of serum sodium and blood-urea to normal concentrations. By the fourteenth postoperative day there was a significant increase ($P < 0·001$) in the total serum protein and albumin to return their concentrations to within the normal range.

The mechanisms underlying the reduction of the ascites are of physiological and pathological interest. It is suggested that cervical lymphovenous shunt has a place in the surgical treatment of intractable ascites.

9. Arrival Time of Bromsulphophthalein (BSP) in the Duodenum—A Method for Assessing Function of the Biliary Sphincter after Sphincterotomy: A. L. G. PEEL (H. D. Ritchie), Surgical Unit, The London Hospital, London.

In an attempt to gain more information about the long-term effects of biliary sphincterotomy the arrival time of injected BSP in duodenal aspirate and the effect of morphine on this was measured.

In 26 patients with a functioning gall-bladder the mean arrival time was $17\cdot4 \pm 6\cdot6$ minutes. Where the gall-bladder did not function (15 patients) or had been removed (30 patients) the mean arrival times were $11\cdot3 \pm 1\cdot9$ and $11\cdot6 \pm 2\cdot2$ minutes respectively ($P < 0\cdot01$). However, in 8 anicteric patients with non-functioning gall-bladders and stones in the duct it was $19\cdot4 \pm 1\cdot2$ minutes.

In 47 of 49 patients who had had cholecystectomy and sphincterotomy 1–12 years previously the time of arrival fell within the above range for cholecystectomized patients, suggesting that bile-flow was not impeded. This was in accordance with clinical, laboratory, and hypotonic duodenography findings. However, in 2 patients with normal liver-function tests it was 19 and 36 minutes respectively which suggests some degree of obstruction to bile-flow.

Morphine prolonged the arrival time by 3–9 minutes in control patients with an intact sphincter and also after sphincterotomy, suggesting that the operation had not completely abolished muscular activity in the sphincter region.

10. The Composition of Bile in Patients with Disease of the Terminal Ileum:

D. C. Smith, R. A. McAllister, and C. Mackay, University Department of Surgery, Western Infirmary, Glasgow.

There is an increased incidence of gall-stones in patients who have undergone resection of the terminal ileum (Heaton and Read, 1969). Fourteen patients with disorders of the terminal ileum were studied; 5 had previously undergone resection and 9 had radiological evidence of Crohn's disease.

Bile was obtained by duodenal intubation and cholecystokinin administration. The concentrations of bile-salt, cholesterol, and phospholipid were estimated and the relative composition of each sample was calculated by the method of Admirand and Small (1968).

In all 5 patients who had undergone resection of the terminal ileum the relative composition of bile lay without the zone of cholesterol solubility. In the remaining 9 patients who each had an intact but diseased terminal ileum the relative composition lay within the zone of cholesterol solubility.

These findings suggest that patients who have undergone resection of the terminal ileum may develop gall-stones because they secrete bile which is supersaturated with cholesterol relative to bile-salt and phospholipid, probably owing to a lack of bile-salt as a result of impaired absorption.

Admirand, W. H., and Small, D. M. (1968), *J. clin. Invest.*, **47**, 1043.

Heaton, K. W., and Read, A. E. (1969), *Br. med. J.*, **2**, 494.

11. Experimental Hepatic Coma and Lethal Barbiturate Intoxication Response to Total-body Asanguineous Hypothermic Perfusion in Dogs:

K. B. Absolon, A. W. Carroll, J. C. Agostini, L. R. Goldbaum, and M. E. Applebaum, Departments of Surgery of the Washington Hospital Center, the George Washington University, and the Hyman Research Foundation, Department of Toxicology, Armed Forces Institute of Pathology, Washington, D.C.

Removal of the total circulating blood-volume and temporary replacement with an asanguineous perfusate under hypothermic conditions was investigated as a method of treatment for acute hepatic insufficiency and lethal barbiturate poisoning.

Biochemical (liver profile, electrolytes, complete blood-count, blood-urea nitrogen, blood-sugar) and physiological (central venous pressure, blood-pressure, electrocardiogram, core body temperature) parameters were studied in two groups of dogs. Ten dogs underwent end-to-side portacaval shunt followed 24 hours later by hepatic artery ligation, while 6 dogs underwent total body asanguineous hypothermic perfusion (T.B.A.P.) in addition within an average of 6 hours following hepatic artery ligation (Rappaport et al., 1953).

In the first group there was a progressive onset of coma and an average rise in blood-ammonia by 3·07 mg. per cent (5·27 mg. per cent initial to 8·34 mg. per cent over the 7 hours preceding death; in the control series blood-ammonia levels averaged 5·37 mg. per cent). The second group presented an average rise of blood-ammonia of 2·92 mg. per cent (9·41 mg. per cent initial to 13·33 mg. per cent) in the 6 hours prior to T.B.A.P., with post-T.B.A.P. ammonia levels decreasing to an average of 7·90 mg. per cent. Following T.B.A.P. all the animals died within 12 to 24 hours, a prolongation of survival by 100–400 per cent.

A series of 10 dogs received toxic doses of phenobarbital intravenously (50–100 mg. per kg. of body-weight) followed by T.B.A.P. after allowing adequate distribution. It was calculated that an average of 25 per cent of the phenobarbital was removed by T.B.A.P.

Rappaport, A., MacDonald, M., and Borowy, Z. (1953), *Surgery Gynec. Obstet.*, **97**, 748.

12. A New Model for Acute Hepatic Failure:

C. D. Derry and M. Slapak, Sears Surgical Laboratory, Harvard Medical School, Massachusetts, U.S.A.

There is a pressing need for a model of acute hepatic failure which is cheap and reproducible and in which only the liver is damaged. A preparation is described in the rat in which periods of hepatic ischaemia can be produced without the need for portal decompression.

Six groups of rats were used. Each received Keflin intramuscularly and dextrose subcutaneously. Using Penthrane inhalation anaesthesia and making use of the rat's segmental hepatic anatomy, an occluding clamp was placed on the blood-supply to 70 per cent of the liver, leaving 30 per cent normally revascularized, thus decompressing the portal circulation. After 20 (group A), 40 (group B), or 60 (groups C, D, and E) minutes of ischaemia the occluding clamp was removed. In groups A, B, and C the 30 per cent erstwhile vascular segment was immediately resected. In group D it was left for 24 hours and then resected. In group E it was left permanently.

All the animals were conscious and ambulant 4 hours after the operation. Animals died with a high SGOT level, abnormal prothrombin times, and a histological picture of acute pericortical necrosis. The mortality in groups A (12 rats), B (16 rats), C (8 rats), D (12 rats), and E (14 rats) was 27, 87, 83, 38, and 14 per cent respectively.

A cheap reproducible model for hepatic necrosis has been described. A 30 per cent vascularized fragment of liver present for only 24 hours exerts a very significant effect on the mortality consequent to prolonged hepatic ischaemia.

13. The Effect of Colectomy on Survival of Rats after 90 Minutes' Hepatic Ischaemia:

K. Chatamara and M. Slapak, Department of Surgery, University of Cambridge.

Non-absorbable oral Kanamycin reduces the mortality of a 90-minute period of hepatic ischaemia in the rat from 94 per cent in control animals to 21 per cent (Slapak et al., 1973). This reduction was probably related to the presence of bacteria in the bowel. The effect of colectomy on the same model has now been investigated. Male Wistar rats were used in three groups, A, B, and C. All the animals received intramuscular cephalin and dextrose-saline subcutaneously. In group A (10 rats) laparotomy was followed by occlusion of a 70 per cent segment of the liver for 90 minutes. The remaining 30 per cent segment served to decompress the portal circulation. During the 90-minute interval total colectomy with ileorectal anastomosis was performed. At 90 minutes the occluding clamp on the blood-supply to the liver was removed and the vascularized 30 per cent segment was resected, leaving the erstwhile ischaemic lobe in place. In group C (10 rats) the 90-minute occlusion was not performed but total colectomy and resection of the 30 per cent segment were carried out. In group B (17 rats) 90 per cent occlusion was performed, the 30 per cent segment being resected.

All the animals regained consciousness and were fully ambulant within 3 hours. In groups A, B, and C 7 (70 per cent), 1 (5 per cent), and 9 (90 per cent) rats survived for over 2 months.

Colectomy lowered a 95 per cent mortality to 33 per cent. This finding supports a major role of intestinal organisms as a factor in acute liver failure.

SLAPAK, M., DERRY, C. D., JONES, E. A., and CUEVAS, O. (1973), *Nature, Lond.*, in the press.

14. Haematological and Pulmonary Disturbances in Septic Shock: G. F. MILLIGAN, J. A. E. MACDONALD, A. MELLON, and I. MCA. LEDINGHAM, University Department of Surgery, Western Infirmary, Glasgow.

The relationship between the haematological and pulmonary disturbances in septic shock has not been defined.

Twenty-one consecutive patients suffering from septic shock were studied prospectively. Thrombocytopenia of less than 150,000 per c.mm. was found in 18 patients and of less than 50,000 per c.mm. in 12 patients. Prolongation of the prothrombin time and of the partial thromboplastin time was noted. Two patients died of haemorrhage. The fibrinogen degradation products were elevated in 18 patients. The bulk of the haematological changes had occurred within the first 12 hours and persisted for 6 days.

An increase in the alveolar arterial oxygen $(A\text{–}a)O_2$ gradient exceeding 100 mm. Hg occurred in 19 patients and was most marked within the first 24 hours. Radiographic evidence of pulmonary oedema was found in 17 patients and was most marked on the third day. There was an almost immediate improvement in the $(A\text{–}a)O_2$ gradient with intermittent positive-pressure ventilation while the radiographic appearances resolved more slowly.

The nature of the coagulation abnormalities indicated a multifactorial deficiency which resolved spontaneously. The pulmonary disturbances were independent of fluid replacement and infection. An explanation for the mechanism of the pulmonary lesion in these patients is that of disseminated intravascular coagulation.

15. Ventricular Function in Canine Haemorrhagic Shock: J. A. E. MACDONALD, G. F. MILLIGAN, A. MELLON, and I. MCA. LEDINGHAM, University Department of Surgery, Western Infirmary, Glasgow.

A cardiac mechanism has been postulated as a factor in refractory shock (Crowell and Guyton, 1962). Shock was induced in three groups of 6 spontaneously breathing greyhounds by bleeding into a reservoir until the mean arterial pressure was 40 mm. Hg. In group I the shed blood was reinfused immediately; in group II hypovolaemia was sustained for 2 hours, while the arterial pressure rose spontaneously to $105 \pm 2{\cdot}4$ mm. Hg (mean ± S.E.); in group III the arterial pressure was maintained at 40 mm. Hg for 2 hours by further exsanguination. Ventricular function was tested before and after shock by rapid infusion of 300 ml. of blood.

After resuscitation groups I and II showed a return to pre-shock haemodynamic values. Group III showed a significant reduction in arterial pressure (33 per cent), left ventricular stroke work (57 per cent), and myocardial contractility (dP/dt_{max} 34 per cent); left ventricular end-diastolic pressure was significantly raised (36 per cent).

Ventricular function curves were constructed for each animal. In groups I and II the curves were comparable before and after shock. In group III the curves were hypo-effective after shock.

Impairment of ventricular function after sustained hypovolaemic hypotension may contribute to the phenomenon of refractory shock.

CROWELL, J. W., and GUYTON, A. C. (1962), *Am. J. Physiol.*, **203**, 248.

16. The Metabolic Response to Abdominal Surgery in a Tropical Environment:* E. A. ELEBUTE (I. D. A. Johnston), Lagos University Teaching Hospital, Lagos, Nigeria.

Nitrogen balance studies were conducted in 17 adult male Nigerian patients who had vagotomy and a drainage operation for chronic duodenal ulceration. In 9 patients intravenous isotonic dextrose and dextrose-saline were given after operation; the remaining 8 patients had intravenous supplements of nitrogen and calories as amino-acids and 50 per cent dextrose. Accurate records of ward temperature and humidity were obtained during the studies. There was an increased amount of urinary nitrogen which showed no correlation with either nitrogen or calorie intake. This indicated an increased catabolism of endogenous protein after surgery. The resulting negative nitrogen balance was abolished by an increased intake of nitrogen and calories. The level of intake required is much higher in the early than in the late postoperative period. A significant negative correlation of maximum air temperature with deviations of nitrogen balance from the nitrogen-balance/nitrogen-intake regression line indicates that higher environmental temperatures may increase the catabolic response.

Comparison of these results with those obtained by Spivey and Johnston (1972) shows that in permanent inhabitants of the tropics surgery of moderate severity produces a metabolic response of similar magnitude to that observed in temperate climates.

SPIVEY, J., and JOHNSTON, I. D. A. (1972), *Br. J. Surg.*, **59**, 93.

17. The Effect of Surgical Operations of Varying Severity on the Secretion of Growth Hormone: P. D. WRIGHT and I. D. A. JOHNSTON, Department of Surgery, University of Newcastle upon Tyne.

Raised levels of serum growth hormone have been recorded after injury (Glick et al., 1965). A study was planned to examine the growth-hormone response to operations of differing degrees of severity.

Three groups each containing 6 patients were studied after inguinal herniorrhaphy (group I), vagotomy and pyloroplasty (group II), and aortofemoral by-pass (group III). Serum growth-hormone levels were measured under fasting conditions and during a 25-g. intravenous glucose-tolerance test. Tests were performed before, during, and at intervals up to 8 days after operation.

There was no increase in serum growth hormone in response to glucose in any group before operation. Fasting growth-hormone levels only rose significantly on the eighth day in group III. There was a significantly increased secretion of growth hormone in response to glucose during surgery which was greatest in group III ($P < 0{\cdot}0025$). The growth-hormone response to glucose remained elevated after surgery. The response in group III was significantly greater than in groups I and II on the third, fifth, and eighth postoperative days.

The secretion of growth hormone is related to the degree of severity of trauma. Changes in growth-hormone secretion correlated with changes in glucose utilization after injury.

GLICK, S. M., ROTH, J., YALOW, R. S., and BESON, S. A. (1965), *Rec. Prog. Hormone Res.*, **21**, 241.

18. Changes in Thyroid Status after Experimental Femur Fracture in the Rat: J. R. RICHARDS (L. H. Blumgart), Departments of Surgery and Physiology, University of Glasgow.

The role of the thyroid gland in the post-injury situation is controversial, largely owing to failure to appreciate potential sources of experimental error. Rats used in this study were kept singly within a sound-proof, temperature-controlled chamber. Behavioural studies were used to select the least stressful methods of estimating thyroxine turnover. A high-protein, low-residue, ultra-low-iodide diet was found necessary to achieve consistent pre-injury results. Using a double-isotope technique (Harland et al., 1972) fracture of the femur resulted in a 35 per cent increase in the thyroxine degradation rate from 0·88 μg. T_4 per 100 g. body-weight per day prior to injury, rising to 1·13 μg. T_4 per 100 g. body-weight after injury. This increase was of short duration, lasting from 0 to 30 hours after fracture, and was found in only 66 per cent of the injury rats, closely associated with a biphasic urinary nitrogen excretion pattern after injury.

In a separate study, using a modification of Oppenheimer's method (Sterling and Brenner, 1966), femur fracture was found to cause a rise in the serum 'free thyroxine' from 1·3 ± 0·3 ng. per 100 ml. before injury to 3·4 ± 0·6 ng. per 100 ml. after injury. Here there was an initial peak at 6 hours, but the maximum values occurred between 36 and 48 hours and had returned to the pre-injury values by 72 hours.

19. The Measurement of Extracellular Fluid Volume with Radiobromide Simultaneous Plasma and Lymph Disappearance in Man: J. R. W. GUMPERT and R. M. ZOLLINGER, jun. (A. G. Riddell), Department of Surgery, Bristol Royal Infirmary, Bristol, and The Peter Brent Brigham Hospital, Boston, Massachusetts, U.S.A.

Most work with tracer-dilution techniques in body-fluid distribution has been concerned with information obtained after the achievement of equilibrium (tracer statics). There is increasing interest in the study of decreasing tracer concentration during the process of equilibration (tracer kinetics). The unusual opportunity of simultaneously studying the kinetics of radiobromide in plasma and lymph, unhampered by urine loss, in the human presented itself.

Five fasting nephrectomized patients maintained on haemodialysis with thoracic duct fistulae (T.D.F.) received 30 μc. of $Na^{82}Br$ intravenously. Arterial blood and T.D.F. lymph were sampled simultaneously 25 times each over 5 hours.

After correction for the delay in lymph-flow up to the T.D.F., equilibrium between plasma and lymph occurs between 7 and 11 minutes. Thereafter lymph and plasma behave as one compartment.

Lymph and plasma disappearance was compared by graphic analysis and serial exponential subtraction. It is concluded that the first rate constant in radiobromide equilibration is a summation of mixing within the plasma and that part of extracellular fluid exemplified by thoracic duct lymph. Despite the absence of urinary loss, there are two further rates of transfer, possibly representing penetration further into the extracellular space and into the cells respectively.

20. Factors Determining Marker Concentration during Continuous Blood-volume Measurement during Haemorrhage and Infusion: J. M. T. GRIFFITHS (A. N. Smith), Department of Clinical Surgery, University of Edinburgh and Edinburgh Northern Hospital Group.

A method is described of monitoring bleeding from a concealed source by the changing plasma concentration of ^{125}I human serum albumin (H.S.A.) with a measured infusion.

The principal physiological parameters affecting single-dose marker concentration under conditions of haemorrhage and fluid replacement were examined in the baboon as follows:—

1. In 6 animals time/concentration curves for simultaneously injected ^{51}Cr-labelled red cells and ^{125}I H.S.A. were obtained. During the 10-minute equilibration period ^{125}I (blood) activity decreased 22·5 ± 2·9 per cent relative to ^{51}Cr activity. Over the next 3 hours ^{51}C activity fell 0·5 ± 0·2 per cent and ^{125}I, 9·6 ± 1·1 per cent.

2. Transcapillary refilling of the circulation was measured following acute haemorrhages of 10–30 per cent of the blood-volume in 12 experiments. The mean results of three simultaneous methods (^{51}Cr R.B.C. concentrations, ^{125}I H.S.A., microhaematocrit) suggested a two-component curve with almost immediate replacement of 10–15 per cent of the loss.

3. In 9 experiments the net loss of fluid from the circulation was measured during sequential small haemorrhages replaced by Dextran 70. Between 9·5 and 54 per cent of the infused fluid volume had disappeared after 3 hours.

It is concluded that the methodology is valid and that it demonstrates early and substantial fluid transfer across the capillary wall during haemorrhage and infusion.

21. Early Results of Jejuno-ileostomy for Massive Obesity: R. M. BADDELEY, General Hospital, Birmingham.

Because of failure to respond to conventional dietary régimes 60 consecutive massively obese patients were submitted to jejuno-ileostomy. There were 51 women and 9 men who were 75–150 per cent above standard body-weight. Endocrine causes were excluded and routine haematology, serum iron, folic acid and vitamin-B_{12} estimations, serum electrolytes, liver-function tests, and serum cholesterol, calcium, and magnesium levels were measured.

Jejuno-ileostomy was performed after the method of Payne and Dewind (1969), in which the proximal part of the jejunum, measuring 35 cm., was anastomosed to the terminal ileum 10 cm. from the ileocaecal valve. The duration of follow-up was 3–42 months.

There was 1 death (1·7 per cent). At 3 months the average weight-loss was 20·7 kg., at 6 months 31·0 kg., and at 1 year 44·0 kg. There were 4 cases of acute fatty liver, 1 of which was fatal. Transient difficulties were experienced with diarrhoea and vomiting during the first 3 months. The only significant biochemical abnormalities were folic-acid deficiency in 19 patients, low serum iron in 27 patients, elevation of SGOT in 13 patients, low magnesium in 6 patients, and low calcium in 2 patients. These abnormalities were corrected. The results are regarded as satisfactory and further trial of the operation seems justified.

PAYNE, J. H., and DEWIND, L. T. (1969), *Am. J. Surg.*, **118**, 141.

22. Preliminary Comparison of Results following the Intramural Inoculation of Crohn's Disease and Normal Ileal Homogenates in Rabbit Bowel:

D. R. CAVE, S. KANE, and D. N. MITCHELL (B. N. Brooke), Surgical Unit, St. George's Hospital Medical School, London.

Human Crohn's disease and normal ileal tissues were obtained from comparable sites at elective surgery. Homogenates were prepared in normal saline from each frozen tissue. Identical volumes of these homogenates were injected at comparable sites into the wall of the terminal ileum in each of three groups of New Zealand white rabbits. The following observations were made at 3-monthly intervals: (*a*) changes in weight; (*b*) changes in the macroscopic appearances of the terminal ileum and related mesentery; (*c*) histological changes were assessed 'blind' by two independent observers from a full-thickness biopsy of the terminal ileum.

Granulomatous changes with the presence of focal epithelioid and giant-cell granulomas were observed to evolve in the submucosa and other tissues of the bowel wall and in the draining mesenteric nodes of a proportion of rabbits receiving Crohn's disease tissue but *not* in those receiving normal ileal homogenate.

The results of these studies are compatible with the evidence for a transmissible agent from Crohn's disease tissues (Mitchell and Rees, 1970).

MITCHELL, D. N., and REES, R. J. W. (1970) *Lancet*, **I**, 168.

23. Jejuno-ileal Colonic Interposition (J.I.C.I.) following Massive Small-bowel Resection (S.B.R.) in Rats:

D. A. LLOYD (J. Terblanche), Department of Surgery, Groote Schuur Hospital and University of Cape Town, South Africa.

Massive S.B.R. in man results in serious malabsorption. This study in rats assesses the value of colonic interposition between the jejunal and ileal remnants at the time of resection. Eighty-two rats were grouped according to the length of the remaining small bowel (group I, 100 per cent, 75–100 cm.; group II, 20 per cent; group III, 10 per cent) and the surgical procedure performed (S.B.R. alone, with iso- or antiperistaltic J.I.C.I., or with a reversed segment of terminal ileum).

Weight-gain following S.B.R. was increased by isoperistaltic J.I.C.I. and impaired by antiperistaltic J.I.C.I. Transit times of barium from the stomach to the caecum assessed radiologically were 110 minutes in group I and 45 minutes in group II with or without isoperistaltic J.I.C.I. In group III the transit time of 20 minutes was doubled by iso- or antiperistaltic J.I.C.I. ($P > 0\cdot05$).

After S.B.R. radio-isotopic studies showed normal sodium-iodide absorption and impaired absorption of human albumin, triolein, and vitamin B_{12}. Isoperistaltic J.I.C.I. increased the absorption of all the test substances. Antiperistaltic J.I.C.I. increased albumin (large dose only) and triolein absorption but further impaired vitamin-B_{12} absorption.

Compensatory morphological changes occurred in the residual small bowel in all groups after S.B.R. Features suggestive of intestinal obstruction were present proximal to reversed segments of colon and ileum.

These results indicate that isoperistaltic J.I.C.I. improves intestinal absorption following massive S.B.R. in rats and may be a useful procedure in man.

24. The Role of Humoral Factors and Diamine Oxidase Activity in Shock after Intestinal Ischaemia in Rabbits:

J. KUSCHE, H. RICHTER, R. HESTERBERG, and W. LORENZ, Division of Experimental Surgery and Pathological Biochemistry, University Surgery Clinic, Marburg/Lahn, Germany.

The revascularization after superior mesenteric artery occlusion (S.M.A.O.) produces shock due to the release of vasoactive substances. Diamine oxidase (DAO) may protect against such substances, and therefore the influence of a simple perfusion of the ischaemic gut and of the inhibition of DAO on the survival time of rabbits was investigated. The DAO activity was measured using ^{14}C-putrescine as substrate (Okuyama and Kobayashi, 1961).

The small intestine of rabbits contained a high activity of DAO ($2\cdot2 \pm 1\cdot0$ mU. per g. of tissue, $n = 10$). The injection of the specific DAO inhibitor, aminoguanidine (25 mg. per kg. i.v.), into rabbits (anaesthetized with 10–20 mg. per kg. pentobarbitone) 1 hour before S.M.A.O. reduced the survival time from 187 ± 104 minutes in the control group ($n = 10$) to 55 ± 27 minutes after a S.M.A.O. of 90 minutes ($n = 10$, $P < 0\cdot005$). This decrease was dependent on the dose of aminoguanidine. In 30 rabbits under the same conditions the survival time was 153 ± 59 minutes after saline injection, but 134 ± 57, 64 ± 17, 49 ± 22, and 37 ± 15 minutes following 10, 30, 50, and 100 mg. of aminoguanidine per kg. The perfusion of the ischaemic gut by Ringer's solution (37° C., 120 ml. per kg.) and the elimination of the perfusate through a catheter in the portal vein prolonged the survival time from 15 ± 4 to 114 ± 7 minutes ($P < 0\cdot005$, $n = 20$).

OKUYAMA, T., and KOBAYASHI, Y. (1961), *Archs Biochem. Biophys.*, **95**, 242.

25. Myoelectrical Activity in the Recto-sigmoid in Man:

I. TAYLOR, H. L. DUTHIE, B. H. BROWN, and R. SMALLWOOD, University Departments of Surgery and Medical Physics, Royal Infirmary, Sheffield.

By means of intraluminal suction electrodes the myoelectrical activity and associated pressure changes in the rectum and sigmoid have been studied in 60 subjects at rest. The electrical activity in this area possesses two distinctive characteristics which have not so far been observed in recordings from other areas of the gastro-intestinal tract.

1. The slow wave activity is not present all the time. In the lower rectum it is regularly present for an average of 67 per cent of the recording time (range, 36–100 per cent). In the more proximal areas of the bowel it is present for an average of 25 per cent of the recording time (range, 10–52 per cent).
2. There are two rhythms. The most commonly observed one has a frequency between 6 and 9 cycles per minute and an amplitude ranging between 0·25 and 1 mV. The other rhythm has a slower frequency (3–4 cycles per minute) but a higher amplitude (0·6–2·5 mV.).

26. Use of the Leucocyte-migration Test to demonstrate Specific Cellular Immunity in Lymph-nodes draining Colorectal Cancer:

P. J. GUILLOU and G. R. GILES, University Department of Surgery, Leeds (St. James's) University Hospital, Leeds.

A two-stage technique for the demonstration of specific cellular immunity to tumour-associated antigen in lymph-node lymphocytes by the technique of leucocyte-migration inhibition has been developed. A simple one-stage procedure has been used to study sensitization of peripheral blood lymphocytes.

In 5 patients undergoing laparotomy for benign gastro-intestinal disease no inhibition of migration has been observed in response to either normal colonic mucosal (N.C.M.E.) or colonic carcinoma extract (C.C.E.) whether cultured in autologous or homologous AB serum. Of 6 patients with colorectal carcinoma studied so far, 5 showed significant sensitization of peripheral blood lymphocytes to C.C.E. when cultured in AB serum, but only 2 of these showed sensitization in autologous serum. No inhibition of migration was observed in response to N.C.M.E.

Sensitization to N.C.M.E. was not demonstrated in control lymph-nodes or in mesenteric nodes from patients with cancer. However, in the patients with cancer 5 of the 6 nodes from the root of the mesentery exhibited sensitization to C.C.E. but only 3 of the 6 nodes directly draining the tumours were sensitized to the tumour extract.

It is concluded that although lymphocytes are readily sensitized to colonic carcinoma antigen the immune responses of the cells residing in the lymph-nodes in close proximity to the tumour may be impaired by the neoplasm itself.

27. Can a Heterotopically Placed Segmental Liver Graft be Fully Life-supporting? An Affirmative Finding: T. Maki and M. Slapak, Sears Surgical Laboratory, Harvard Medical School, Massachusetts, U.S.A.

Auxiliary liver transplantation for temporary hepatic support would provide optimal liver function for extended periods of time. The use of an auxiliary graft fed by renal, rather than portal, vein blood as the only means of support was studied. In order to examine these questions unhindered by the variables imposed by rejection a new technique of autotransplantation was devised.

Ten 18–22-kg. dogs were used. In group A (5 dogs) two lobes of the liver comprising 40 per cent of the total liver mass were autotransplanted followed by a portacaval shunt and resection of the remaining liver. In group B the left central and left lateral lobes were also transplanted heterotopically but the right lateral and caudate lobes (30 per cent of the liver) were left intact. A portacaval shunt was not performed.

In group A all 5 dogs survived longer than 6 days. One animal died on the sixth day and the other animals were killed on days 63, 84, 113, and 114 respectively whilst in excellent health. At sacrifice a mean increase of 67 per cent had occurred in the graft.

In group B, 5 out of 7 dogs survived for more than 2 months. Of these, 3 were sacrificed on days 91, 74, and 41 respectively. The other 2 animals had resection of the orthotopically placed lobes and a portacaval shunt on days 104 and 18 respectively. Both are alive and healthy.

Renal vein blood instead of portal vein blood can be used in a temporary life-supporting auxiliary liver transplant, and a 40 per cent graft is adequate to maintain healthy life in such circumstances.

28. Phosphate Compounds as Bone-scanning Agents: S. P. F. Hughes, K. Jeyasingh, P. Lavender, and J. I. Burn, Departments of Surgery, Medical Physics, and Radiodiagnosis, Hammersmith Hospital, London.

Both strontium 87^{m} and fluorine 18, the two agents conventionally used for skeletal scintigraphy, have their disadvantages. Recently, phosphate compounds labelled with the readily available isotope technetium 99^{m} have been introduced as possible bone-scanning agents. The comparative merits of the compounds currently available, (1) pyrophosphate, (2) tripolyphosphate, and (3) ethylhydroxydiphosphonate (EHDP), have been investigated by studying these substances in rabbits and dogs and in patients with malignant disease.

The mean blood-levels in rabbits 4 hours after intravenous injection were as follows: tripolyphosphate, 25 per cent; pyrophosphate, 8 per cent; EHDP, less than 2·4 per cent. EHDP gave the best bone : blood ratio of radioactivity at 4 hours, with an impressively high mean value of 47·60. The ratio for pyrophosphate was 39·80 and that for tripolyphosphate was 5·99.

The skeletal scintiscans obtained with EHDP were of superior quality, with good delineation of normal bone in dogs and clearly defined deposits in patients with metastatic disease.

29. Anti-tumour Effects of *Corynebacterium parvum*: J. E. Castro, Division of Surgical Science (Transplantation Biology Section), Clinical Research Centre, Northwick Park, Harrow.

Corynebacterium parvum has inhibitory effects on some mouse tumours (Woodruff and Boak, 1966) and it has been suggested as a therapeutic agent for human tumours.

The effect of *C. parvum* on a syngeneic, transplantable, methylcholanthrene-induced sarcoma of Balb/C mice has been investigated. Intraperitoneal *C. parvum* significantly increased survival when given before or 1 week after intraperitoneal tumour challenge, and there was a good dose–response curve. The anti-tumour effect of *C. parvum* was maintained for 50 days after injection, and prior thymectomy or antilymphocyte serum did not abrogate the anti-tumour effect, suggesting a mechanism of action independent of cell-mediated immunity.

After giving *C. parvum* there was decreased cell-mediated immunity as shown by prolonged allograft survival, decreased graft-versus-host disease, thymus atrophy, and a decrease of θ-positive cells. In contrast, there was increased macrophage activity associated with splenomegaly and hepatomegaly, but prior splenectomy had no effects on the tumour protection afforded by *C. parvum*.

It is concluded that *C. parvum* has powerful anti-tumour effects mediated through increased macrophage function.

Woodruff, M. F. A., and Boak, J. L. (1966), *Br. J. Cancer*, **20**, 345.

30. Cellular Immunity to Malignant Melanoma: R. M. Grant, A. J. Cochran, C. E. Thomas, R. M. Mackie, D. E. Cameron-Mowat, and W. G. S. Spilg (J. N. Norman), University Departments of Pathology and Dermatology, the Western Infirmary, Glasgow.

The usefulness of the leucocyte-migration inhibition test in the measurement of cell-mediated immune responses was assessed in patients with malignant disease.

The effect of tumour extracts on the migration of peripheral blood leucocytes from 55 patients with malignant melanoma and 63 control donors was examined. The leucocytes from the majority of tumour-bearing patients (60 per cent) were inhibited on contact with extracts of histogenetically similar tumours but only occasionally by extracts of dissimilar tumours and normal tissues (8 per cent). Leucocytes from control donors were rarely inhibited by any of the tissue extracts (14 per cent). A striking decline in the frequency of tumour-extract-mediated inhibition of leucocyte migration was associated with advanced disease.

Cell-mediated immunity to tumour-associated antigens was measured in 22 patients in the early postoperative period, 16 of these cases having also been studied prior to surgery. Twelve of these 16 cases tested preoperatively showed significant inhibition of migration on contact with extracts of histogenetically similar tumours. Of the 22 cases studied in the early postoperative period, only 1 had significant inhibition of leucocyte migration. Significant inhibition of leucocyte migration returned in most patients within 5–22 days of operation.

31. Effects of Hyperthermia in Advanced Malignancy: C. M. Ludgate, R. T. Pettigrew, J. M. Galt, D. B. Horn, and A. N. Smith, Hyperthermia Unit and Departments of Anaesthetics and Clinical Chemistry, Western General Hospital and University of Edinburgh.

Human total-body hyperthermia to 42° C. has been produced in attempts to cause tumour necrosis. Energy is introduced at the rate of 3000–5000 cal. per minute during immersion in molten wax and ventilation under deep narcosis with a helium/oxygen mixture at 80° C. (Henderson and Pettigrew, 1971). Twelve patients had intensive physiological studies. There was an initial and sustained increase in the heart-rate, but an initial rise in the blood and central venous pressures was not maintained. Fluid and electrolyte losses were high but could be replaced using a standard intravenous régime. The serum bilirubin rose by an average of 0·13 mg. per 100 ml., but not above 0·6 mg. per 100 ml. if the temperature did not exceed 41·8° C. with no change in the serum-enzyme levels. Above this temperature the latter (SGOT, SGPT, and LDH) rose by 50 per cent and the serum bilirubin to 1·3 mg. per 100 ml. The tumours which responded most favourably to thermotherapy were sarcomas, and relief of pain was common.

HENDERSON, M. A., and PETTIGREW, R. T. (1971), *Lancet*, **1**, 1275.

32. Cutaneous Delayed Hypersensitivity Responses to 2-4-Dinitrochlorobenzine—A Prognostic Guide in Malignant Disease: G. BONE, D. R. APPLETON, and C. W. VENABLES, Department of Surgery, University of Newcastle upon Tyne.

An accurate assessment of the prognosis in individual patients with cancer would be valuable in planning treatment. It is possible that cellular immunity may have a role in restricting the progress of malignant disease (Burnet, 1970).

A study was set up to investigate the relationship of cellular immunity in 70 patients suffering from gastro-intestinal tract cancer and their survival. Cellular immunity was assessed by measuring the patient's ability to produce a cutaneous delayed hypersensitivity response to four different strengths of 2-4-dinitrochlorobenzine after initial sensitization with this chemical (Eilber and Morton, 1970).

Over a 6-month follow-up there was a highly significant ($P < 0{\cdot}001$) relationship between good cellular immune responses and a favourable prognosis.

It is suggested that this test will prove of value in the surgical management of patients with gastro-intestinal malignancies, in that radical surgery would not appear to be justified in patients with a greatly diminished cellular immune response.

BURNET, F. M. (1970), *Immunological Surveillance*. Oxford: Pergamon Press.
EILBER, F. R., and MORTON, D. L. (1970), *Cancer*, **25**, 362.

33. The Influence of Transplantable Tumours on the Healing of Colonic Anastomoses in the Rat: R. J. STEWART and J. I. MACNAUGHTON (H. Ellis), Westminster Hospital, London.

The early healing of colonic anastomoses in Sprague-Dawley rats bearing a Walker carcinoma, a Novikoff hepatoma, or a Yoshida sarcoma has been investigated.

In 200 animals, randomly divided into groups of 10, anastomoses were constructed in the proximal colon using a standard technique. Rats bearing between 10^4 and 10^8 tumour cells, as estimated at the time of anastomosis, were compared with control animals. The tumour cells were implanted either at the site of anastomosis (local) or in the dorsal subcutis (distant).

Healing was assessed on the seventh postoperative day by histology, hydroxyproline estimations (Woessner, 1961), and bursting strength measurements (Nelsen and Anders, 1966). The serum total protein, urea, electrolytes, and haemoglobin were also estimated.

Significant impairment of healing was noted when at least 10^5 Walker cells, 10^6 Novikoff cells, or 10^7 Yoshida cells were present locally at the time of anastomosis. However, 10^7 Walker cells or more than 10^8 Yoshida cells were required to cause similar impairment when distant from the wound. In all the groups bursting strength fell linearly with total serum protein.

NELSEN, T. S., and ANDERS, C. J. (1966), *Archs Surg., Chicago*, **93**, 309.

34. A Method of Evaluation of Renal Preservation Techniques: G. A. MCLOUGHLIN, R. A. SELLS, and I. M. TYRRELL, Department of Surgery, University of Liverpool.

Successful renal preservation depends upon the maintenance of cell-volume homeostasis. Change in the intracellular water during preservation provides an estimate of cell-volume change and an index of preservation efficacy at the cellular level.

Canine kidneys subjected to 30 minutes' warm ischaemia were preserved either by an ice-flush technique (Collins C_4) or continuous perfusion at 9° C. with one of several different perfusates (either cryoprecipitated plasma or purified protein fraction (P.P.F.) with or without additives). Cortical biopsies were taken during 36 hours' cold ischaemia, and by estimation of the total tissue water and extracellular fluid (inulin) space (Flear et al., 1960) the intracellular water was derived.

No significant difference was found in the mean increase in intracellular water between ice-flush and cryoprecipitate perfusion for cold ischaemic periods of up to 12 hours ($P > 0{\cdot}4$). For longer cold ischaemic periods cryoprecipitate perfusion was significantly more effective in arresting cell swelling than the ice-flush technique ($P < 0{\cdot}001$). P.P.F. perfusion was significantly better than all other methods for all periods of cold ischaemia ($P < 0{\cdot}001$). The addition of glucose, hydrocortisone, insulin, and magnesium to either cryoprecipitated plasma or P.P.F. made no significant difference ($P > 0{\cdot}4$ and $P > 0{\cdot}2$ respectively). Only the addition of 15 mEq./l. of potassium to P.P.F. significantly reduced the mean increase in intracellular water for all cold ischaemic periods ($P < 0{\cdot}001$).

FLEAR, C. T. G., CRAMPTON, R. F., and MATHEWS, D. M. (1960), *Clin. Sci.*, **19**, 483.

35. Renal Preservation by Hypothermic Perfusion—The Importance of Pressure Control: C. J. GREEN and D. E. PEGG, Animal Division and Division of Cryobiology, Clinical Research Centre, Harrow, Middlesex.

The best combination of physical variants in a perfusion system designed for renal graft preservation is uncertain. Experiments were designed to study systematically the influence of different perfusion parameters in order to decide whether perfusion should be by constant pressure or constant flow.

Experiments were performed on isolated rabbit kidneys which were preserved for 24 hours and then autografted into the donor animal with immediate contralateral nephrectomy. A defined perfusate (Pegg and Green, 1972) designed to mimic rabbit plasma was used and the temperature was controlled at 5° C. throughout the 24-hour period. A direct comparison was made between 10 kidneys perfused at a constant pressure of 40 mm. Hg and 10 kidneys perfused at a constant flow of 13 ml. per minute. Vascular resistance and organ weight were recorded continuously and changes in perfusion composition were monitored. Subsequent function was assessed by ability to support life, by measurement of urea and creatinine levels at 2-day intervals, and finally by histological appearance at autopsy.

The kidneys in the constant-pressure group scored significantly better on all counts but particularly in their blood-urea-handling capacity. It is concluded that constant-pressure is preferable to constant-flow perfusion.

PEGG, D. E., and GREEN, C. J. (1972), *Cryobiology*, **9**, 420.

36. The Effect of Allopurinol in sparing ATP, ADP, and AMP in Anoxic Kidneys:

T. V. KEAVENY, S. K. CUNNINGHAM, and P. FITZGERALD, Department of Surgery, University College, Dublin.

Vasko et al. (1972) postulated that the protective effect of allopurinol in renal ischaemia was through preservation of the nucleotide pool. The effect of allopurinol on the levels of ATP, ADP, and AMP in rat kidneys made anoxic by clamping was studied.

The normal total of ATP, ADP, and AMP was 4·42 ± 0·482 μmol per g. wet weight. Total levels in the kidneys of rats which had received 20 mg. of allopurinol 20 minutes before vascular clamping of 30 minutes' duration (group 3) were significantly greater than the total levels in kidneys of rats similarly treated but with no allopurinol (group 2) (2·169 ± 0·200 and 1·791 ± 0·164 μmol per g. wet weight respectively, $P < 0·0025$). In groups 4 and 5 the kidneys were revascularized for 30 minutes after 30 minutes' clamping. Levels where rats were pre-treated with allopurinol (group 5) were significantly greater than in the untreated group (group 4) (2·541 ± 0·064 and 2·151 ± 0·228 μmol per g. wet weight respectively, $P < 0·01$). Groups 6 and 7 and groups 8 and 9 were similar to groups 2 and 3 and groups 4 and 5 respectively, except that the period of anoxia was extended to 60 minutes. Levels in the allopurinol pre-treatment groups were significantly higher than in the untreated groups (1·694 ± 0·098 compared with 1·257 ± 0·194, $P < 0·0005$; 2·410 ± 0·381 compared with 1·828 ± 0·321, $P < 0·005$, respectively).

The results indicate that allopurinol pre-treatment maintains a higher level of the adenine nucleotide pool in anoxic kidneys.

37. Implantation of Pancreatic Islets into the Portal Vein of Diabetic Rats:

C. B. KEMP, M. J. KNIGHT, D. W. SCHARP, P. E. LACY, and W. F. BALLINGER (B. N. Brooke), Departments of Surgery and Pathology, Washington University School of Medicine, St. Louis, Missouri, U.S.A.

Intraperitoneal implantation of isolated pancreatic islets ameliorates the effects of streptozotocin-induced diabetes in the rat (Ballinger and Lacy, 1972), but normal values for blood-glucose and urine volumes are rarely achieved. As insulin is normally secreted into the portal venous system the effects of intraportal and intraperitoneal siting of implanted islets in diabetic rats has been compared.

Streptozotocin diabetes was induced in 20 inbred Lewis rats. Ten of these rats acting as controls passed between 82 and 186 ml. of urine containing 8·1–15·6 g. of glucose daily, with blood-sugars fluctuating between 320 and 760 mg. per cent. Pancreatic islets isolated by the collagenase-digestion method (Lacy and Kostianovsky, 1967) were implanted intraperitoneally into 5 diabetic rats and directly into the portal vein of 5 other diabetic rats. Urine volume and glucose content as well as blood-sugar levels were monitored regularly.

Rats receiving intraperitoneal islets showed an amelioration of the diabetic state in that urine volumes stabilized between 50-[illegible]50 ml. containing 4–5 g. of glucose daily with blood-sugar levels of 200–410 mg. per cent. Portal vein implantation resulted in normoglycaemia and normal urine volumes without glycosuria which are being maintained 6 weeks later.

These results suggest that the portal system may be the site of maximal effectiveness for transplanted pancreatic islets.

38. The Survival of Transplanted Isolated Pancreatic Islets in the Omentum and Testis:

J. FERGUSON and R. J. SCOTHORNE (I. D. A. Johnston), Department of Anatomy, University of Newcastle upon Tyne.

Isolated pancreatic islets transplanted as allografts into the testis in guinea-pigs may survive for periods of up to 11 weeks—some five to six times longer than orthotopic skin allografts (Ferguson and Scothorne, 1972). The factors thought to be responsible for extended survival were the graft dosage, the special properties of the grafted tissue, or special properties of the testis as a graft site.

A study was planned to assess the relative importance of these factors by three groups of experiments. Skin allografts of varying size were implanted into the testis. Large-dose grafts showed a 28 per cent survival at 21 days and small-dose grafts showed a 100 per cent survival at 28 days. Skin allografts in large and small dosage were implanted into the omentum, which is technically a favourable site and not usually regarded as 'privileged'. Large-dose grafts showed a 33 per cent survival at 21 days and small-dose grafts showed a 100 per cent survival at 28 days. Isolated pancreatic islets were implanted into the omentum. Intra-omental islet-cell allografts were all alive when recovered at intervals from 10 days to 11 weeks.

The results support the view that the extended survival of islet-cell allografts in the testis is probably due to a combination of factors such as the privileged nature of the testis and the fact that islet tissue may be less antigenic than skin or that the survival period is related to 'dose' of tissue grafted.

FERGUSON, J., and SCOTHORNE, R. J. (1972), *Br. J. Surg.*, **59**, 316.

39. Passive Enhancement of Heterotopic Rat Heart Transplants:

P. R. F. BELL and N. L. TILNEY, University Department of Surgery, Western Infirmary, Glasgow.

French and Batchelor (1969) demonstrated an increased survival of renal allografts in rats by passive transfer of specific allo-antiserum. The aim of this study was to define more fully the effects of enhancement using the heterotopic cardiac transplant model in similar inbred rat strains.

AS rats were immunized by 5 weekly intraperitoneal injections of $1–2 \times 10^7$ spleen or lymph-node cells from August donors. Serum was pooled and stored at −20° C. The antibody titre measured by a standard cytotoxic method was consistently 1 : 256.

Hearts from (AU × AS) F_1 donors were transplanted heterotopically to AS recipients. Allografts were rejected by control animals in 8 ± 1 days. Allo-antiserum was administered to test animals using the régime of French and Batchelor (1969). One ml. was given intravenously on completion of the transplant, 1 ml. intraperitoneally at 24 hours, and 0·5 ml. intraperitoneally at 48, 72, and 96 hours postoperatively. Cardiac allografts in these animals have survived with good function for over 100 days.

Serum was collected from enhanced recipients with grafts functioning for at least 50 days and transferred adoptively to a second group of heart-graft recipients using a similar dosage schedule. These hearts continue to beat normally for over 50 days. These observations show that enhancing antibody can successfully prolong heart-allograft survival. In addition, enhanced recipients actively produce their own auto-enhancing antibody.

FRENCH, M. E., and BATCHELOR, J. R. (1969), *Lancet*, **2**, 1103.

40. The Influence of Calcium on Graft Rejection and Immunity to Malignancy:

G. W. ODLING-SMEE (H. W. Rodgers), Department of Surgery, Queen's University, Belfast.

Immunity to all grafts and immunity to malignancy is mediated by lymphocytes. These are cytotoxic for the foreign cells of the graft or the 'non-self' cells of a malignant tumour. Whitfield et al. (1971) have shown that *in vitro* lymphocytes will transform at a lesser rate with a lowered calcium concentration in the media and vice versa. Since cell-mediated immunity is carried out by lymphocytes and since lymphocyte transformation is an accurate *in vitro* correlate of cell-mediated immunity it is suggested that low calcium concentrations depress cell-mediated immunity and, conversely, high concentrations stimulate it.

Experiments were set up to test this hypothesis. Rats had their serum calcium depressed by parathyroidectomy and a calcium-free diet for 15 days. Fifteen out of 20 rats were then able to accept allogeneic skin-grafts. When rats with chemically induced tumours were depleted of calcium in the same way 8 tumours disappeared and 17 tumours regressed out of a total of 27 animals with tumours. The results with the skin-grafts confirm the hypothesis, but the results with malignant tumours suggest that the effect may be due to a direct action of calcium on cell division.

41. A New Bedside Radio-isotope Test for the Detection of Deep Venous Thrombosis in the Legs:

D. A. D'AURIA, G. J. DUFFY, T. G. BRIEN, D. ORMOND, and J. A. MEHIGAN, Department of Surgery, University College, Dublin, and Radio-isotope Department, St. Vincent's Hospital, Dublin.

Macro-aggregates of albumin (^{131}I MMA) have been shown by Webber et al. (1969) to have an affinity for blood-clot. The possibility of detecting venous thrombosis using ^{131}I MMA and a simple portable scintillation detector system (Pitman Isotope Localizing Monitor) which would allow the procedure to be carried out at the bedside has been investigated.

Following the production of acute femoral venous thrombosis in 10 dogs by electrocautery, 20–30 μc. of ^{131}I MMA was injected intravenously distal to the thrombus. The count-rate over the clot area and over the corresponding area on the opposite leg was measured at 5-minute intervals for 20 minutes. There was an increase in radioactivity over the clot area of 20–100 times when compared with the control area. This increase persisted throughout the period of observation.

Fifty-four patients with clinical evidence of deep venous thrombosis were investigated using ^{131}I MMA and the portable scintillation detection system. Approximately 100 μc. of ^{131}I MMA were injected into the deep venous system using tourniquets. Count-rates were obtained at 5-minute intervals for 20 minutes at seven points along the injected leg and at corresponding points on the opposite leg. There was retention of radioactivity in 30 out of 34 limbs (88 per cent) shown by phlebography to contain thrombi. There was rapid clearance of radioactivity in 17 of 20 limbs (85 per cent) for which the phlebograms were normal. There was an 87 per cent agreement between phlebography and the ^{131}I MMA venous clearance test.

WEBBER, M. M., BENNETT, L. R., and CRAGIN, M. (1969), *Radiology*, **92**, 620.

42. Evaluation of Elastic Stockings in Venous Insufficiency:

J. J. F. SOMERVILLE and P. J. BYRNE (W. G. Fegan), Clinical Research Department, Sir Patrick Dun's Hospital, Dublin.

This evaluation was carried out on full-length two-way-stretch elastic stockings. Two groups were studied: (1) 10 normal volunteers and (2) 12 patients with venous insufficiency. Group 1 was studied once and group 2 on four occasions, each separated by 30 days. Stockings were worn continuously for the first 60 days and not worn for the last 30 days. At each visit assessments were made of the severity of symptoms, the venous ambulatory pressures monitored from a superficial foot vein, and the pressure exerted by the stockings.

While walking group 1 reduced their mean superficial venous pressure from 84 to 18 mm. Hg. In group 2 before treatment with stockings the superficial venous pressure fell from 91 to 48 mm. Hg on walking, whereas after wearing stockings for 60 days the patients in this group could reduce their pressure from 91 to 29 mm. Hg on walking. After a further 30 days without stockings they could reduce their pressure to 36 mm. Hg. The improvement with treatment was significant ($P < 0\cdot005$).

There was a highly significant improvement in symptoms ($P < 0\cdot001$) after 60 days' treatment with stockings, and the severity of symptoms correlated closely with venous ambulatory pressures.

Pressures exerted by the stockings showed a decrease from the ankle to the thigh which was maintained between visits.

43. The Organization of Pulmonary Thrombi in relation to Their Site and Time of Origin:

M. T. MORRELL and M. S. DUNNILL, Nuffield Department of Surgery and Gibson Laboratories, Radcliffe Infirmary, Oxford.

The autopsy finding of multiple pulmonary emboli in various stages of organization has been held to indicate recurrent embolism in spite of the lack of corroborative clinical episodes. Secondly, adherent organizing lesions are believed by some to be locally formed thrombi and not emboli.

Experimental evidence for these beliefs was sought in dogs. Thrombi were induced in flowing blood by the thrombogenic action of lead in the inferior vena cava and lobar pulmonary arteries; emboli were released from the former. Twelve dogs had pulmonary emboli, 20 had pulmonary thrombi formed in situ, and 8 had both emboli and thrombi. The dogs were killed at intervals of up to 40 days and the expanded lungs were fixed and then sliced.

The histologist (unaware of the experimental procedure) could not distinguish between locally formed and embolic thrombi at any stage of organization. Although older thrombi tended to show greater organization the more remarkable finding was the wide variation in organization relative to the age of the lesion.

It is concluded that the presence at autopsy of pulmonary emboli with varying degrees of organization may be the result of one embolic episode, and that there is no histological difference between locally formed and embolic pulmonary artery thrombi.

44. Reversal of Lethal Carbon-monoxide Intoxication by Total-body Asanguineous Hypothermic Perfusion:

K. B. ABSOLON, J. C. AGOSTINI, A. P. BASU, S. N. ALBERT, and L. R. GOLDBAUM, Departments of Surgery of the Washington Hospital Center, the George Washington University and the Hyman Research Foundation, Department of Toxicology, Armed Forces Institute of Pathology, Washington, D.C., U.S.A.

The role of total-body asanguineous hypothermic perfusion following the administration of lethal doses of carbon monoxide was investigated (Klebanoff et al., 1972).

Three groups of 5 dogs each were studied. The first group received a 10 per cent mixture of carbon monoxide and room air through an endotracheal tube for 3 minutes (Smith, 1965). The second group underwent total-body asanguineous hypothermic perfusion (T.B.A.P.) only. The third group was similarly intoxicated and treated with T.B.A.P. after signs of irreversible carbon-monoxide intoxication were evident.

The first group of dogs suffered cardiorespiratory arrest within 1 hour of exposure to the gas, averaging carboxyhaemoglobin concentrations of 80 per cent (70–100 per cent) prior to death. The group treated by T.B.A.P. alone showed only evidence of haemodilution and all survived. The third group was subjected to carbon monoxide, and their carboxyhaemoglobin concentrations averaged 72·8 per cent (52–86 per cent); as soon as signs of anoxia appeared they underwent T.B.A.P. Following T.B.A.P. their carboxyhaemoglobin concentrations dropped to an average of 8·12 per cent (1–15 per cent) and all the animals survived. The average time to T.B.A.P. was 19·8 minutes (14–30 minutes).

This study shows that the severe systemic hypoxia resulting from carbon-monoxide intoxication can be completely reversed by the rapid removal of the circulating carboxyhaemoglobin by T.B.A.P. with no sequelae.

45. Gastrin Release in Response to Oral Glucose in Patients before and after Gastric Operations: R. C. G. Russell, J. P. S. Thomson, S. R. Bloom, and M. Hobsley, Department of Surgical Studies, The Middlesex Hospital, London.

Evidence for the effect of oral glucose on gastrin release before and after gastric operations is inconclusive. Accordingly, 19 preoperative patients and 74 postoperative (truncal vagotomy, 26; selective vagotomy, 29; partial gastrectomy, 19) duodenal ulcer patients were studied. Fasting and serial blood samples after oral glucose (200 ml., 50 per cent solution) were taken and the plasma-gastrin concentration was measured by radioimmunoassay.

The mean basal plasma-gastrin concentration was 19·3 pg. per ml. in the preoperative patients, 12·7 pg. per ml. in those after partial gastrectomy, and 42·6 pg. per ml. in those after vagotomy, this latter value being significantly higher ($P < 0·01$) than the preoperative mean. In these three groups the plasma-gastrin concentration increased after glucose ingestion. There was no difference in this increase between truncal vagotomy and selective vagotomy and between those with and without dumping symptoms. In the vagotomy group only a significant ($P < 0·01$) 'rebound' fall in plasma gastrin below the fasting level was observed at 120 minutes, at which time the plasma gastrin was insignificantly different from the preoperative group.

These results indicated that gastrin is released following a pure carbohydrate meal, that the gastrin release is greatest in patients having had vagotomy in whom there is a significant but unexplained fall below the fasting level at 120 minutes, and that gastrin is not related to the dumping syndrome.

46. The Effect of Transit through the Gastric Fundus on Circulating Gastrin: J. C. W. Evans, D. D. Reeder, and J. C. Thompson (J. H. Peacock), Department of Surgery, University of Texas Medical Branch, Galveston, Texas, U.S.A.

The organs responsible for the rapid catabolism of gastrin have yet to be accurately identified. The effect on circulating levels of endogenous gastrin of transit through the gastric fundus has been studied during basal conditions and conditions of stimulated gastrin release in 14 anaesthetized dogs. Gastrin release was stimulated by antral perfusion with acetylcholine.

During basal conditions transit through the gastric fundus resulted in no significant loss of gastrin, being 108 ± 15 pg. per ml. in the arterial serum and 99 ± 10 pg. per ml. in the venous serum. During antral stimulation gastrin levels rose in both arterial and venous samples, but concentrations were significantly lower in all of the venous samples compared with the arterial samples. The average arterial concentration of gastrin during this period was 278 ± 11 pg. per ml. while the average venous concentration was 208 ± 13 pg. per ml. ($P < 0·05$).

The subsequent introduction of acid into the antrum caused both arterial and venous levels to fall to almost basal levels and abolished the significant difference between arterial and venous levels.

It is concluded that the gastric fundus is an important site for the inactivation of elevated levels of circulating gastrin.

47. Serum-gastrin Levels following Pylorus-preserving Gastrectomy: T. Hennessy (W. G. Fegan), Department of Surgery, University College, Cork.

The technique of pylorus-preserving gastrectomy requires the retention of a 2-cm. cuff of antrum proximal to the pylorus. The effect of retaining this antral cuff was studied.

Ten patients with chronic duodenal ulcer had serum-gastrin levels estimated in the fasting state and after stimulation with a standard protein meal. Six weeks after pylorus-preserving gastrectomy the estimations were repeated.

The mean fasting level of gastrin fell from a preoperative figure of 35 ± 5·2 pg. to 16 ± 8 pg. after operation ($P = 0·005$).

The mean peak stimulated level was reduced from 118 ± 31·4 pg. to 21 ± 6·6 pg. after operation ($P = 0·0005$).

It was concluded that gastrin secretion from the retained antral cuff was unlikely to be a factor in precipitating recurrent ulceration after pylorus-preserving gastrectomy.

48. Operative Measurements of Cerebral Blood-flow (C.B.F.) and Internal Carotid Artery (I.C.A.) Pressure during Carotid Ligation: P. J. Leech, W. Fitch, J. Barker, and J. D. Miller, Medical Research Council Cerebral Circulation Research Group, Institute of Neurological Sciences, Glasgow.

Eighteen normotensive patients with intracranial aneurysms underwent temporary clamping of the internal and then the common carotid arteries while C.B.F. and I.C.A. pressure measurements were made to assess the probability of ischaemic complications following ligation.

C.B.F. reduction of more than 25 per cent may be associated with immediate or delayed hemiparesis (Jennett et al., 1966). Using this criterion in the past a low incidence of ischaemia has been achieved, but since the cost was the rejection of 39 per cent of patients for permanent ligation a review of the method was undertaken.

In this series a correlation between C.B.F. reduction and I.C.A. pressure reduction was observed ($P < 0·001$) but the scatter was too wide to predict C.B.F. reduction accurately from the I.C.A. pressure reduction.

Ligation was safe during temporary clamping when the C.B.F. exceeded 40 ml. per 100 g. per minute or when the I.C.A. pressure exceeded 60 mm. Hg, but was always unsafe with a C.B.F. of less than 20 ml. per 100 g. per minute. In the C.B.F. range 20–40 ml. per 100 g. per minute, using I.C.A. pressure with C.B.F. reduction, enabled a higher proportion of patients to be successfully ligated than was possible using C.B.F. alone. By utilizing this revised method 15 patients were ligated in this series and none suffered a permanent neurological deficit.

Jennett, W. B., Harper, A. M., and Gillespie, F. C. (1966), *Lancet*, **2**, 1162.

49. Human and Computer-aided Diagnosis of 'Dyspepsia': J. C. Horrocks and F. T. de Dombal, Department of Surgery, University of Leeds.

This paper reports an evaluation of and comparison between various modes of diagnosis and their ability to discriminate between diseases such as duodenal ulcer, gastric ulcer, cholecystitis, and gastric cancer. A prospective unselected series of 168 patients with upper abdominal pain was studied. For each patient we recorded the initial diagnosis in the out-patients department, the final preoperative diagnosis after full investigation, the computer's diagnostic prediction based solely upon the house-surgeon's *interview* (excluding findings on examination), and the final operative diagnosis.

Overall the initial (out-patient) diagnosis was 52·8 per cent accurate, the computer's diagnostic prediction was 86·8 per cent accurate, and the final preoperative diagnosis was substantiated at operation in about 91 per cent of cases. These results suggest that a computer-aided system may have something to offer the unaided clinician, that it offers no diagnostic advantage over radiography although it is much quicker and cheaper, and that the *history* is crucial in dyspepsia, and may form a basis for future studies in which the case history might be elicited by a 'physician's assistant'.

50. The Feasibility of Scaling up the Space for Implantable Prosthetic Lungs: J. L. Wosornu and D. G. Melrose, Hammersmith Hospital, London.

Previous experiments in rats showed that a reproducible technique could create an artificial gas cavity (a skin-lined hemithorax) which the rats could ventilate (Wosornu and Melrose, 1971). The validity of these conclusions has been tested in larger animals. The aim was to provide space inside the chest cavity which could safely house implantable prosthetic lungs.

Autogenous skin capsules were grafted into the pleural spaces of 6 pigs of mean weight 16·0 ± 1·6 kg. They all survived ($P < 0{\cdot}016$). Their mean weight was 32·4 ± 2·6 kg. 3 weeks after intrapleural skin-grafting. The skin capsule enlarged to occupy the left hemithorax, closely reproducing its contour.

The skin-lined hemithorax was opened to the exterior 5 weeks later to create an artificial gas cavity. Among the variables monitored were arterial pressure (M.A.P.), electrocardiogram, arterial *p*H, Po$_2$, and Pco$_2$, and ventilation. Paired data were obtained in 4 pigs, before (A) and 2 hours after (B) creation of the stoma in the chest wall.

	M.A.P. (mm. Hg)	Heart-rate (per min.)	Arterial		
			*p*H	Po$_2$	Pco$_2$
A	70 ± 4	150 ± 7	7·346 ± 0 009	78·2 ± 6·4	45·7 ± 1·8
B	73 ± 5	158 ± 5	7·316 ± 0 023	57·4 ± 2·8	45·3 ± 3·3
P(d.f. = 3)	0·39	0·05*	0·38†	0 014*	0·92†

* Significant.
† Not significant.

Ventilation in the normal hemithorax was 85 ± 10 ml. per kg. per minute compared with 40 ml. per kg. per minute in the skin-lined hemithorax ($P < 0{\cdot}001$).

It is thus feasible to scale up the space for implantable prosthetic lungs, and the conclusions drawn from the rat are valid for larger animals.

Wosornu, J. L., and Melrose, D. G. (1971), *Br. J. Surg.*, **58**, 865.

51. Amine Levels in the Cerebrospinal Fluid after Subarachnoid Haemorrhage: B. H. Cummins and D. Lothian (J. H. Peacock), Frenchay Hospital, Bristol, and Department of Surgery, Bristol Royal Infirmary.

Spasm of the cerebral arteries complicates about one-third of cases of subarachnoid haemorrhage. This paper reports the levels of noradrenaline, adrenaline, and 5-hydroxyindole acetic acid (5HIAA) found in the cerebrospinal fluid (C.S.F.) after subarachnoid haemorrhage using a modified spectrofluorimetric technique.

Information on normal levels of catechol amines in human C.S.F. is sparse. C.S.F. from 9 cases of minor neurological disorders was studied. The mean value of noradrenaline was 0·181 ± 0·075 μg. per litre and of adrenaline was 0·041 ± 0·044 μg. per litre, in agreement with Klensch and Gott (1970).

C.S.F. and plasma levels of 35 cases of subarachnoid haemorrhage were studied concurrently with carotid angiography. No spasm was present in 22 cases, and in these cases the catechol amines were within normal limits (noradrenaline 0·154 ± 0·069 μg. per litre, adrenaline 0·045 ± 0·070 μg. per litre). In 7 cases where spasm was present but localized to the aneurysm site the noradrenaline level was raised (0·341 ± 0·185 μg. per litre). Six cases showed intense spasm. In these cases the C.S.F. noradrenaline content was 0·764 ± 0·355 μg. per litre which is very significantly above normal values ($P < 0{\cdot}001$).

The C.S.F. level of noradrenaline was not dependent upon the plasma level. Neither the adrenaline nor the 5HIAA levels were significantly raised in these 35 cases.

It is considered that the presence of excess noradrenaline in the C.S.F. may contribute to cerebral arterial spasm.

Klensch, H., and Gott, U. (1970), *Klin. Wschr.*, **14**, 853.

52. Controlled Trial of Wound Spraying with Poly-antibiotic or Povidone Iodine Aerosols: O. J. A. Gilmore (R. B. Welbourn), Royal Berkshire Hospital, Reading.

Four hundred and fifty consecutive appendicectomies through grid-iron incisions done in a district general hospital were included in a controlled trial of wound spraying as a prophylactic measure against postoperative wound infection. The infection rate was reduced by about one-half ($P < 0{\cdot}02$).

Patients were allocated randomly to one of three groups: (1) no spray (control), (2) sprayed with a poly-antibiotic aerosol (Dispray containing neomycin sulphate, zinc bacitracin, and polymixin B sulphate), (3) sprayed with a povidone iodine aerosol (Disadine D.P. giving 5 per cent available iodine). The surgeon was informed of the spraying procedure after he had removed the appendix and closed the peritoneum. Bacteriological swabs were taken from the appendix and from the wound before spraying. The wounds were inspected on the sixth post-operative day and after 1 month by observers who were unaware of the spraying procedure used.

When there were organisms on the appendix wall, wound contamination occurred seven times more frequently than when there was none. Contaminated wounds which were not sprayed became infected ten times more frequently than non-contaminated wounds.

Spraying with either spray reduced infection in all age-groups and in enlarged, drained, contaminated, and non-contaminated wounds.

GROUP	TOTAL No.	INFECTED		SIGNIFICANCE
		No.	Per cent	
Control	151	24	16·0	—
Poly-antibiotic aerosol	150	14	9·3	$P < 0\ 06$
Povidone iodine aerosol	149	12	8·0	$P < 0\cdot 25$

53. **Abnormal Reactions to Suture Materials and Wound Infection:** M. G. LORD (H. B. Torrance), Manchester Royal Infirmary, Manchester.

Various authors have demonstrated abnormally severe reactions to various suture materials. This paper demonstrates that in patients with this abnormal reaction there is a statistically significant incidence of wound infection and dehiscence.

Two hundred patients undergoing clean elective abdominal surgery had each of three materials (thread, chromic catgut, and nylon) inserted into the skin of the lower abdominal wall. The erythema around the materials was measured with dividers in two diameters at right-angles on days 1–5 postoperatively. The abdominal wound was sutured with the same materials.

Two groups of patients emerged. One group had minimal reaction around the sutures. All 15 patients in this group had terminal carcinoma and died within 14 days of operation. Another group had severe reactions of over 16 mm.

Of the 200 patients, 21 had infected wounds and dehiscence; 16 of these had severe reactions to one of the trial sutures. Eleven patients had severe reactions in the non-infected wound group ($P < 0\cdot 001$).

The conclusions drawn from these observations are that in certain cases severe reaction to suture materials contributes to wound infection and dehiscence. This reaction may be a delayed-type hypersensitivity reaction, explaining why no antibodies to suture materials are found in animals sensitized to them.

54. **What is the Optimal Dose of Insulin for Use in the Hollander Test?:** S. DAVIES, P. J. LYNDON, and D. JOHNSTON, University Department of Surgery, General Infirmary, Leeds.

It is important to choose the correct dose of insulin because side-effects such as cardiac irregularities, epileptiform convulsions, and coma sometimes occur and may occasionally be fatal. Careful dose–response studies by Baron (1969) and Isenberg et al. (1969) suggested that the optimal dose of insulin was 0·2 U. per kg. However, in many subjects maximal peak 30-minute acid output (P.A.O.^{I}) is elicited by 0·1 U. per kg.

In this study each subject underwent two insulin tests on separate days. In one test the dose was always 0·2 U. per kg. In the other it was either 0·1 or 0·125 U. per kg. Tests were done in random order. Insulin was given by rapid intravenous injection. Subjects were normal volunteers, patients with duodenal ulcer, and patients more than 1 year after vagotomy. Blood-glucose levels were measured serially and any side-effects were noted.

The dose of 0·1 U. per kg. proved inferior to 0·2 U. per kg. because in 7 paired tests the P.A.O.^{I} was much less in 3 tests and equal in 4. However, the dose of 0·125 U. per kg. proved as effective as 0·2 U. per kg. in stimulating acid output and in lowering blood-glucose. In paired tests in 10 subjects with intact vagi the smaller dose of insulin elicited P.A.O.^{I} of $24\cdot 28 \pm 3\cdot 48$ mEq. per hour and the larger dose $24\cdot 85 \pm 2\cdot 84$ mEq. per hour ($P < 0\cdot 02$). In paired tests in 10 patients after vagotomy P.A.O.^{I} was $2\cdot 79 \pm 0\cdot 92$ mEq. per hour (0·125 U. per kg.) and $2\cdot 87 \pm 0\cdot 85$ mEq. per hour (0·2 U. per kg., $P < 0\cdot 02$). One subject was Hollander 'negative' with the smaller dose, but 'positive' with the larger dose.

These results suggest that a dose of insulin of 0·125 U. per kg. may be 'optimal'.

55. **Reproducibility of Pepsin Output and Plasma Gastrin Concentration after Insulin in Peptic Ulcer Patients:** D. I. WALKER, J. B. ELDER, P. C. GANGULI, and I. E. GILLESPIE, University Department of Surgery, Manchester Royal Infirmary.

Little is known of the reproducibility of gastric pepsin output or of the plasma-gastrin concentration response following insulin-induced hypoglycaemic cholinergic stimulation.

In 12 peptic ulcer patients gastric juice obtained by nasogastric tube after a 12-hour fast was collected for four 15-minute intervals before and at eight 15-minute periods after the injection of soluble insulin, 0·2 U. per kg., and assayed for peptic activity by the method of Piper (1960); samples of venous blood were withdrawn at similar time intervals for measurement of plasma-gastrin concentration by the radio-immunoassay method of Ganguli and Hunter (1972). A repeat test was performed on each subject within 1 month.

Significant correlations between tests 1 and 2 were obtained for the mean 15-minute basal pepsin outputs before insulin ($r = 0\cdot 86$, $P < 0\cdot 005$) and for pepsin outputs in the first and second hours after insulin ($r = 0\cdot 87$, $P < 0\cdot 005$ and $r = 0\cdot 74$, $P < 0\cdot 05$ respectively). The best correlation between paired samples for pepsin output was obtained at 75 minutes after insulin injection ($r = 0\cdot 89$, $P < 0\cdot 001$).

Paired plasma-gastrin concentrations showed significant correlations for the mean 15-minute basal samples ($r = 0\cdot 51$, $P < 0\cdot 025$), but following insulin injection no significant correlations were found for paired 15-minute values.

These results suggest that the gastric pepsin response to insulin hypoglycaemia is more consistent for successive tests than is the plasma-gastrin concentration response, and that insulin may not be an adequate stimulus for the production of endogenous gastrin secretion.

56. **The Evaluation of Gastric Pepsin Output to Insulin in Patients with Recurrent Ulcer:** J. B. ELDER, D. I. WALKER, and I. E. GILLESPIE, University Department of Surgery, Royal Infirmary, Manchester.

Venables (1970) suggested that gastric pepsin output may be used as a discriminant in patients with recurrent ulceration. This hypothesis has been re-examined in 35 preoperative duodenal ulcer (D.U.) patients, 20 patients with proven recurrent ulcers (R.U.), and 14 patients who were symptom-free (S.F.) at 6–12 months after truncal vagotomy and drainage, all the groups being matched for age and weight. Each patient had an insulin test (0·2 U. per kg. i.v.) with measurement of the acid output on samples collected at 15-minute intervals by titration to *p*H 7, and of total proteolytic activity at *p*H 2 (Piper, 1960).

Patients with recurrent ulcers produced significantly more pepsin in the basal hour secretion (115 ± 30 mg.) than the symptom-free group (51 ± 10 mg., $P < 0\cdot 05$).

In the preoperative D.U. group the mean peak 30-minute output after insulin (499 ± 58 mg.) was significantly greater than that observed in the R.U. group (226 ± 54 mg.) and than that in the S.F. group (121 ± 50 mg., $P < 0\ 0005$).

Analysis using the ratios of peptic activity in stimulated : basal secretion gave the following results: D.U., $20·3 \pm 2·9$; R.U., $13·3 \pm 2·8$; S.F., $8·9 \pm 2·6$.

The use of absolute values resulted in better discrimination between the groups than did the use of ratios, and significant differences in peptic activity between groups of patients were noted.

57. Inhibition of Human Gastric Secretion by Orally or Intravenously Administered Prostaglandin 16, 16 Dimethyl-E_2 Methyl Ester: D. C. CARTER, S. M. M. KARIM, D. BHANA, and P. A. GANESAN (A. P. M. Forrest), Departments of Surgery and Pharmacology, Edinburgh, and Makerere University, Kampala, Uganda.

Inhibition of human acid secretion by orally administered prostaglandin analogues has been reported (Carter et al., 1973) but to date no effective inhibition of gastric secretion has been reported following bolus i.v. injection of prostaglandins.

The synthetic compound prostaglandin 16, 16 dimethyl-E_2 methyl ester was given orally in the dose range 25–200 μg. to 23 healthy male volunteers and by bolus i.v. injection in the dose range 3·125–50 μg. in 16 subjects. When compared with control tests in the same subjects a highly significant mean reduction in the basal acid output of 92 per cent ($P < 0·001$) followed the oral administration of 200 μg. of prostaglandin analogue and a mean reduction of 77 per cent followed the i.v. injection of 50 μg. ($P < 0·001$).

When 200 μg. of the analogue were given orally in association with pentagastrin (6 μg. per kg. i.m.) the mean M.A.O. in response to pentagastrin alone was reduced by 66 per cent in 7 subjects ($P < 0·01$). Similarly, i.v. injection of 25 or 50 μg. of the analogue in 12 subjects brought about a mean reduction of 54 and 83 per cent ($P < 0·001$) respectively in the mean M.A.O. to pentagastrin alone.

It is concluded that this compound is a potent inhibitor of basal and pentagastrin-induced acid secretion when given orally or intravenously to male volunteers.

58. The Failure of Intra-arterial Vasopressin to break the Canine Gastric Mucosal Barrier: N. J. DORRICOTT and W. SILEN (G. Slaney), Departments of Surgery, Beth Israel Hospital, Boston, U.S.A., and Queen Elizabeth Hospital, Birmingham.

Ischaemia can break the gastric mucosal barrier to H^+ ions and may contribute to gastric ulceration (Skillman et al., 1970). Selective intra-arterial infusion of vasopressin is used in the treatment of gastro-intestinal haemorrhage (Nusbaum et al., 1969). Experiments to investigate the effect of intra-arterial vasopressin on the gastric mucosal barrier of the standing awake dog have been carried out.

The arteries of Heidenhain pouches in 5 antrectomized dogs were selectively catheterized in 9 experiments. Net 30-minute fluxes of H^+ and Na^+ were measured when the pouches were perfused with 100 m*M* HCl before, during, and after vasopressin was infused via the arterial catheter at 12 U. per hour for 3 hours. Gastric mucosal blood-flow was measured by aminopyrine clearances.

Vasopressin infusion decreased secretion of H^+ and Na^+ from control values of 24 ± 22 and 117 ± 17 Eq. per 30 minutes respectively to produce back-diffusion of H^+ to -28 ± 20 Eq. per 30 minutes associated with a secretion of Na^+ of 52 Eq. per 30 minutes after 3 hours. However, net fluxes of H^+ were not significantly different from control values or associated with an increase in Na^+ secretion to indicate breaking of the gastric mucosal barrier. Ischaemia of the gastric mucosa during vasopressin infusion was confirmed by a fall in the mucosal blood-flow from a mean control of $1·6 \pm 0·92$ ml. per minute to $0·25 \pm 0·12$ ml. per minute.

It is concluded that intra-arterial vasopressin at 12 U. per hour does not break the canine gastric mucosal barrier after 3 hours.

59. Increased Faecal Excretion of Bile-acids in Post-vagotomy Diarrhoea: V. P. GERSKOWITCH, J. G. ALLAN, and R. I. RUSSELL (L. H. Blumgart), Departments of Gastroenterology and Surgery, Royal Infirmary, Glasgow.

The pathogenesis of severe post-vagotomy diarrhoea is uncertain. Excessive amounts of dihydroxy bile-acids in the colon stimulate water and electrolyte secretion and cause diarrhoea (Mekhjian et al., 1971).

The role of bile-acids in post-vagotomy diarrhoea has been evaluated by measuring their faecal excretion in patients with severe symptoms, in patients after vagotomy and drainage operations but with no diarrhoea, and in normal control subjects.

Seven subjects with post-vagotomy diarrhoea were studied; all had undergone operation 1–8 years prior to the study and had continuous watery diarrhoea. Three patients had increased daily faecal fat excretion but all had normal jejunal mucosal histology.

The mean total faecal bile-acid excretion measured over 5 days in patients with post-vagotomy diarrhoea by gas–liquid chromatography was 2538 ± 632 mg. per day (range, 1044–5222 mg.). These results are significantly higher than those in the normal control subjects (mean, 671 ± 128 mg. per day; range, 311–1059 mg.; $P < 0·02$). Individual bile-acids in the post-vagotomy diarrhoea group and the normal control subjects were as follows: cholic acid, 232 and 26 mg.; deoxycholic acid, 1290 and 377 mg.; chenodeoxycholic acid, 438 and 83 mg.; lithocholic acid, 705 and 185 mg. respectively. Statistically significant increases were found in the excretion of deoxycholic ($P < 0·05$) and chenodeoxycholic acid ($P < 0·001$).

Excessive amounts of bile-acids in the colon (notably dihydroxy acids) may be a factor in the pathogenesis of post-vagotomy diarrhoea.

60. The Duodenal Brake—Hormonal or Vagal?: M. SHAHIDULLAH, T. L. KENNEDY, and T. G. PARKS, Royal Victoria Hospital and The Queen's University, Belfast.

The loading effect of acid, sugar, and fat on the rate of gastric emptying in man has been reviewed by Hunt and Knox (1966).

To investigate the mechanisms involved, dogs were prepared with gastric and duodenal fistulae. Gastric emptying was measured by the dye-dilution method of George (1968). HCl, dextrose, and fat left the stomach significantly slower than water ($P < 0·001$).

Another dog model was prepared by dividing the duodenum immediately beyond the intact pylorus, which was implanted 50 cm. below the duodenal stump. A 600-ml. water meal left the stomach in 52 minutes. When water, acid, dextrose, or fat was placed in the stomach each meal emptied at the same rate. However, when acid, dextrose, or fat was added to the duodenal loop, emptying of water from the stomach was 75, 133, and 181 minutes respectively ($P < 0·001$). Following truncal or extragastric selective vagotomy the braking mechanism remained intact.

When 500 ml. of blood taken from a dog 30 minutes after the introduction of fat into the duodenum were transfused into a fasting animal a twofold increase in the emptying time of a water meal resulted ($P < 0·001$). The braking mechanism may be hormonally rather than vagally mediated.

61. The Effects of varying the Extent of Vagotomy on the Canine Gastric and Duodenal Myoelectrical Activity: C. J. STODDARD, B. H. BROWN, and H. L. DUTHIE, University Surgical Unit, Sheffield Royal Infirmary, and Sheffield Regional Medical Physics Department.

Transthoracic vagotomy in dogs is followed by a temporary disorganization of the gastric myoelectrical activity (Kelly and Code, 1969) and in humans this disorganization is related to the extent of the vagal denervation (Stoddard et al., 1973). The aim of this study was to assess the changes in the canine gastric and duodenal myoelectrical activity after graded abdominal vagal denervation.

Six Ag–AgCl electrodes were attached to the serosa of the stomach and duodenum in 4 dogs and exteriorized via a metal cannula. Recordings of 5 hours' duration were made after an 18-hour fast and, on separate occasions, the characteristics of the electrical activity were observed following a meat meal. All the dogs had a pyloroplasty performed prior to vagotomy. One dog received a truncal vagotomy (T.V.) alone and the other 3 had a highly selective vagotomy (H.S.V.) which was converted to a T.V. 6 weeks later.

Pyloroplasty had no effect on the myoelectrical activity. T.V. alone produced a permanent disorganization of the gastric pace-setter potential (P.S.P.). Following H.S.V. there was a temporary decrease in frequency of the gastric P.S.P. and a persistent diminution of its amplitude but no disorganized activity. The succeeding T.V. only produced transient disorganization of the P.S.P. Following T.V. and H.S.V. the normal myoelectrical responses to feeding were impaired. Changes in the canine gastric myoelectrical activity are thus dependent on the extent of the vagotomy.

62. Effect of Vagotomy on Co-ordination of the Interdigestive Myoelectrical Complex of the Antrum and Duodenum: I. H. KHAN and B. S. BEDI, University Department of Surgery, Western Infirmary, Glasgow.

The electrical activity can be used as an index of motility of the gastro-intestinal tract (Daniel and Chapman, 1963). This activity has a regular pattern in the small intestine and is controlled by the extrinsic nerves (Carlson et al., 1972). The purpose of the present study was to investigate the effect of vagotomy on the pattern and the co-ordination of electrical activity of the stomach and duodenum.

Three mongrel dogs were prepared with chronically implanted Ag–AgCl electrodes on the serosal surface of the stomach and duodenum. The electrical activity was detected in healthy, fasted, and conscious dogs.

Prolonged recordings of the myoelectrical activity showed periods when no action potentials (phase I) were present and this was followed by periods (phases II, III, and IV) with varying numbers and amplitudes of action potentials. Each cycle (phases I–IV), lasting for 105 minutes, started in the stomach and propagated into the duodenum. Each phase of the cycle in the stomach and duodenum was well co-ordinated across the gastroduodenal junction. Pyloroplasty had no effect on this co-ordination. Total vagotomy with previous pyloroplasty caused disruption of the phases and loss of co-ordination between the complexes of the stomach and duodenum.

These experiments show that the vagus nerves control the co-ordination of the interdigestive myoelectrical complex across the gastroduodenal junction.

63. Objective Assessment of Electrical Treatment of Stress Incontinence: C. D. COLLINS (J. H. Peacock), Department of Surgery, Bristol Royal Infirmary.

Urethral pressure profiles were measured in 18 normal subjects and 32 stress-incontinent patients under three conditions: at rest, during voluntary contraction of the pelvic floor muscles, and during the Valsalva manœuvre. Comparison of urethral length and maximal pressure-profile measurements revealed a significantly ($P < 0·05$) shorter length and lower pressure under each of the three test conditions in the stress-incontinent group. This indicated that urethral pressure-profile measurements might show a change in patients treated successfully by electrical stimulation.

Fifteen stress-incontinent female patients had been treated with intermittent electrical stimulation and physiotherapy (Collins, 1972) over 1 year previously, of whom 8 were symptomatically cured and 5 were improved. In the cured group only the urethral length measurement during the Valsalva manœuvre showed a significant increase ($P < 0·05$) over pre-treatment levels.

These results suggest that successful treatment acts by improving pelvic floor muscle function. This reduces the degree of shortening of the urethra which occurs in the stress-incontinent patient when intra-abdominal pressure is increased.

COLLINS, C. D. (1972), *Proc. R. Soc. Med.*, **65**, 832.

64. Non-invasive Measurement of the Slope of the Arterial Pressure Curve in the Lower Extremities of Patients with Arterial Occlusion: K. W. JOHNSTON and V. V. KAKKAR, Departments of Surgery, University of Toronto, Canada, and King's College Hospital Medical School, London.

There is no ideal non-invasive method to assess patients with peripheral arterial occlusion. This paper describes a non-invasive technique from which the systolic pressure slope (S.P.S.) in the leg can be calculated and it may be applied to the assessment of arterial occlusion.

The R wave of an E.C.G. was used to signal the onset of a cardiac cycle, and the arrival of a pulse wave was recorded in the foot by an electrical impedance plethysmograph. A blood-pressure cuff at the ankle was inflated and as the pressure in the cuff increased above diastolic pressure the onset of the pulse wave was delayed in reference to the onset of the cardiac cycle (R wave). From the cuff pressure change and the recorded delay of arrival of the pressure wave the S.P.S. was calculated.

The S.P.S. was measured in 41 limbs of 30 patients and the extent of their arterial disease was classified by arteriography and clinical examination. The results were as follows: normal subjects (11 limbs), 645 ± 128 mm. Hg per second; patients with stenosis but no symptoms (8 limbs), 428 ± 123 mm. Hg per second; patients with occlusion (22 limbs), 133 ± 89 mm. Hg per second.

Non-invasive measurement of the S.P.S. distinguishes between normal limbs, those with symptomatic stenosis, and those with arterial occlusion ($P > 0\cdot001$), and is of potential value in the haemodynamic assessment of patients with peripheral vascular disease.

65. The Relationship between Doppler Ultrasound Assessment and Angiography in Occlusive Arterial Disease of the Lower Limbs:

P. L. Harris, L. A. Taylor, F. D. Cave, P. C. Williams, G. P. Naylor, and D. Charlesworth, Departments of Surgery and Physics, University Hospital of South Manchester.

Audiofrequency analysis of Doppler-shifted ultrasound was used to determine the pulse-wave velocity (P.W.V.), the pulsatility index (P.I.), and the damping factor (D.F.) in 45 patients and 30 asymptomatic volunteers. All the patients had an aortogram prior to reconstructive arterial surgery. Each arterial segment was graded according to the severity of the disease as seen on the arteriogram. The common femoral P.I. was related to angiographic grading in the aorto-iliac segment; there were significant differences between all the grades ($P < 0\cdot001$). In the femoropopliteal segment there was a significant difference in the popliteal P.I. between each grade ($P < 0\cdot001$). The tibial P.I. was not closely related to angiographic appearance but the difference between patients and normal volunteers was highly significant ($P < 0\cdot001$).

The D.F. in occluded femoropopliteal segments was significantly higher than in normal subjects ($P < 0\cdot001$) but in the popliteal to pedal segment the D.F. was not related to angiographic appearance. P.W.V. was not closely related to angiographic grading at any site.

The P.I. may be related to angiographic appearances and where there are differences they may reflect the limitations of aortography.

66. Lysozymuria following Aortic Surgery:

S. J. A. Powis, G. Slaney, and J. D. Blainey, Department of Surgery, Queen Elizabeth Hospital, Birmingham.

Lysozyme is a low molecular weight protein (M.W., 15,000) derived predominantly from leucocytes. It normally passes into the glomerular filtrate and undergoes almost complete reabsorption in the proximal tubules. Acute tubular necrosis which occasionally complicates major surgery is associated with lysozymuria. The frequency of renal tubular damage as judged by urinary lysozyme estimations in patients undergoing aortic surgery was investigated.

Twenty-one patients were studied for the first 10 days postoperatively. Twelve patients were operated on electively for abdominal aortic aneurysms or severe obliterative aorto-iliac disease. Nine patients had emergency operations for leaking abdominal aortic aneurysms.

Of the 12 patients having elective operations, 9 showed elevation of the urinary lysozyme level. This was short-lived (mean, 2·5 days) and only 4 patients had levels above 5 μg. per ml. (normal < 1·2 μg. per ml.). There was no clinical evidence of significant renal failure in any patient.

All of the patients having emergency operations had elevated urinary lysozyme levels, the duration being longer than in the elective group (mean, 4·5 days), and 6 of the 9 patients had levels in excess of 5 μg. per ml. All 9 patients had elevated blood-urea levels, and urine volume was abnormal in 3 patients.

Some degree of renal tubular damage which is related to the severity of the operation commonly follows major aortic surgery. However, this is not always clinically manifested.

67. Significance of Raised Plasma Fibrinogen in 95 Patients with Intermittent Claudication:

J. A. Dormandy, T. L. Dormandy, and D. Arrowsmith, Department of Surgery, Royal Free Hospital, and Department of Chemical Pathology, Whittington Group, London.

Ninety-five patients with intermittent claudication have been studied for up to 3 years (65 for over 1 year). In addition to full clinical assessment the calf blood-flow has been measured before and after a standard exercise at 2-monthly intervals. Whole-blood viscosity, plasma fibrinogen, and all lipid parameters were determined on blood taken simultaneously.

The commonest biochemical abnormality was a raised plasma fibrinogen; 57 (60 per cent) of the patients had a fibrinogen above 400 mg. per cent (2 standard deviations above the normal mean). The mean plasma fibrinogen of the patients was 428 ± 122 mg. per cent.

The initial fibrinogen level of individual patients correlated well with the severity and progress of the disease, as assessed by claudication distance ($R = 0\cdot44$, $P < 0\cdot01$). The mechanism of this effect may be related to changes in blood viscosity as there was also a positive correlation between plasma fibrinogen and whole-blood viscosity measured at 230 sec.$^{-1}$ ($r = 0\cdot39$, $P < 0\cdot005$).

These results suggest that the most important biochemical abnormality in intermittent claudication may be a raised plasma fibrinogen and that this may be related to the state and progress of the disease by its influence on blood viscosity.

68. The Evaluation of an Intravenous Fat-tolerance Test in assessing Fat Turnover in Surgical Patients:

J. G. W. Feggetter, H. A. Davidson, D. Appleton, and I. D. A. Johnston, Department of Surgery, University of Newcastle upon Tyne.

An intravenous fat-tolerance test has been used to measure the removal rate of fat in patients with hypertriglyceridaemia (Boberg et al., 1969). A study was planned to investigate fat turnover in patients before and after surgery.

Thirty-five patients admitted for elective surgery were studied. A bolus injection of a commercial fat emulsion (Intralipid 20 per cent) was administered intravenously in a dose of 150 mg. per kg. body-weight. Serial blood samples were taken and the serum-clearance rate was measured nephelometrically (Lewis et al., 1972). Elimination is by first-order kinetics (a constant fraction of plasma triglyceride is removed per unit time) so that a semi-logarithmic plot gives a straight line from which the slope K_2 may be calculated. The value K_2 per cent per minute represents the patient's rate of removal of fat (triglyceride) which may be related to utilization.

The mean K_2 value in preoperative patients was found to be 4·23 per cent per minute (range, 1·60–6·86 per cent per minute). The hyperbolic relationship between the K_2 value and the fasting triglyceride previously noted (Boberg et al., 1969) was confirmed and found to be significant at the 5 per cent level. Forty-eight hours after surgery the serum triglyceride had fallen by a mean 59·8 mg. per 100 ml. ($P < 0\cdot05$) and the mean K_2 value had increased by 2·51 per cent per minute ($P < 0\cdot001$).

The increased clearance of fat emulsion may be due to utilization which is increased for several days after surgery. This test may thus be a measure of the metabolic response to surgery.

69. Studies of the Precision and Accuracy of Gastric Secretory Tests for the Determination of Acid Reduction following Vagotomy: W. LORENZ, H. TROIDL, H. ROHDE, G. ACKER, and W. SEIDEL, Division of Experimental Surgery and Pathological Chemistry, University Surgery Clinic, Marburg/Lahn, Germany.

After vagotomy a medium reduction of the maximum acid output (M.A.O.) of about 50–70 per cent was observed, but in a few cases, some with insulin-negative responses, there was almost no reduction. Since these exceptions could be caused by technical errors or biological variations, studies on the precision and accuracy of gastric secretory tests in non-operated duodenal ulcer patients were carried out as follows:—

1. *Quality control for the titration*: Using mixed gastric juice from 50 patients 10-ml. portions were frozen at −20° C. and the acid was determined daily over 6 months. Average and range control charts were constructed according to Gooszen (1960).

2. *Duplicate gastric tests in 80 patients*: The M.A.O. in response to 6 μg. pentagastrin per kg. i.m. was recorded according to Baron (1970).

3. *Dose–response curves with pentagastrin*: In 40 of the patients studied under (2) the response to 6, 12, and 15 μg. pentagastrin per kg. was recorded.

Within a single day the coefficient of variation for the titration was only 1·2 per cent ($n = 10$) and within 6 months it was 0·8 per cent ($n = 112$), indicating a high precision of the test. Also the reproducibility of the pentagastrin test (6 μg. per kg.) was excellent for the whole group (test 1: 251 ± 98 ml. per hour and 29·2 ± 14·1 mEq. per hour; test 2: 243 ± 100 ml. per hour and 29·5 ± 16·7 mEq. per hour) but not for single patients, since 15 per cent of the subjects showed differences of more than 40 per cent (maximum 84 per cent). Furthermore, the accuracy of M.A.O. was not guaranteed, because 38 per cent of the patients secreted 18–33 per cent more acid following 12 μg. pentagastrin per kg. than after 6 μg. per kg.

70. The Role of a High-residue Diet in the Treatment of Diverticular Disease of the Colon: T. G. PARKS, Department of Surgery, The Queen's University, Belfast.

Gastro-intestinal transit rates were measured in 24 patients with diverticular disease of the colon while on a low-residue diet containing less than 3 g. daily of indigestible fibre. Subsequently the transit rates were reassessed in the same patients when stabilized on a high-residue diet incorporating a bran supplement. The fibre content of this régime was 12 g. daily. The technique described by Hinton et al. (1969) of using radio-opaque polythene pellets for assessing intestinal transit rate was modified in the present study, and for comparison simultaneous measurements were made using ^{51}Cr-labelled sodium chromate.

The time interval from ingestion to recovery of the first markers, and of 20, 50, and 80 per cent of the markers was assessed. The mean transit time while on the low-residue diet was 43·6 hours compared with 37·2 while on the high-residue régime ($P < 0·01$). The mean wet weight of faecal residue was 96 g. daily on a low-residue diet compared with 176 g. on a high-residue diet ($P < 0·001$). The corresponding mean daily dry weights were 19·6 and 34·2 g. respectively.

It is concluded that a diet incorporating a high-fibre content leads to a significant increase in the transit rate as well as in the bulk of the faeces.

71. Human and Computer-aided Diagnosis of Lower Gastro-intestinal Disorders in 468 Patients: F. T. DE DOMBAL, D. J. LEAPER, J. C. HORROCKS, J. R. STANILAND, S. E. CLAMP, and A. P. MCCANN, University Department of Surgery and the Centre for Computer Studies, University of Leeds.

This paper reports a comparison between various diagnostic modes in respect of lower gastro-intestinal disorders, such as large-bowel cancer, diverticular disease, Crohn's disease, and ulcerative colitis. In a retrospective series of 300 patients the computer's overall accuracy was 79·7 per cent, and subsequently a prospective unselected consecutive series of 168 patients was studied. For each patient we recorded the initial clinical diagnosis, the final preoperative diagnosis after full investigation, the computer's diagnostic prediction based largely upon the house-surgeon's case notes, and the final histopathological diagnosis.

Overall, in 168 patients the computer's diagnostic prediction proved accurate in 89·5 per cent. This compares with an initial clinical diagnostic accuracy of 69·5 per cent and a final accuracy after full investigation of 87·6 per cent. Most of the computer's errors were in misclassifying Crohn's disease and ulcerative colitis, and in predicting cancer the computer was 95·7 per cent accurate.

These results suggest that using a simple diagnostic-aided system inexperienced surgeons may approach the diagnostic effectiveness of their more experienced colleagues.

SHORT NOTES OF RARE OR OBSCURE CASES

PRIMARY RETROPERITONEAL HYDATID CYST

BY S. MUKERJEE, M. NIGAM, AND J. C. SARAF
WILLINGDON HOSPITAL, NEW DELHI, INDIA

SUMMARY

A case of a primary retroperitoneal hydatid cyst in an Indian adult which was treated by marsupialization is described. Attention is drawn to the rarity of the lesion, the probable mode of spread, and the difficulties encountered in its diagnosis.

THE word *Echinococcus* is of Greek origin and means hedgehog berries because the multiple cysts resembling berries and hooklets seen on laboratory examination present a bristling appearance. The word 'hydatid' is also of Greek origin and means a drop of water. It was first applied by Rudolphi in 1810.

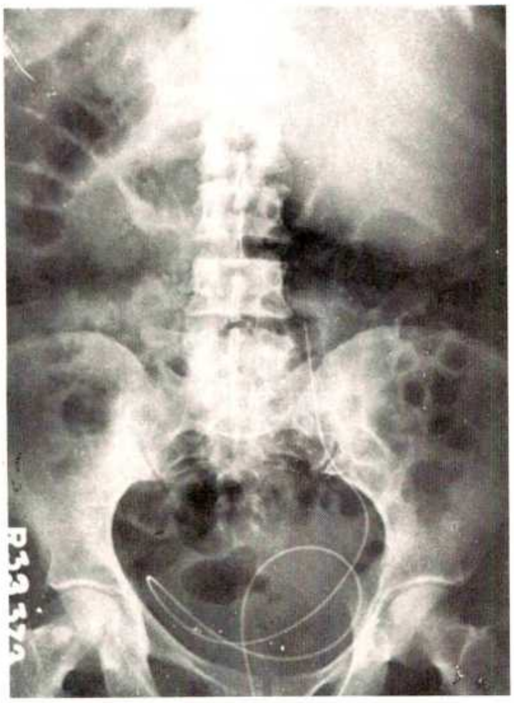

FIG. 1.—Plain radiograph of the abdomen showing a circumscribed soft-tissue shadow in the left hypochondrium and loin.

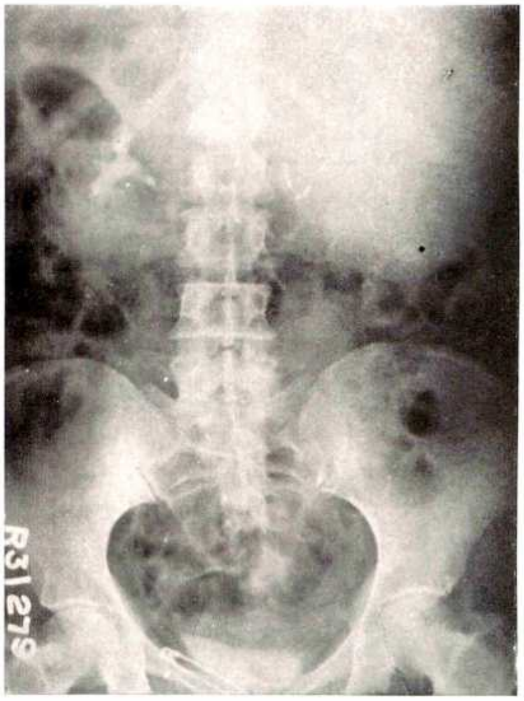

FIG. 2.—Intravenous pyelogram showing a non-functioning left kidney.

Redi in 1664 first suspected the animal origin of hydatid cysts. The course of these cysts was not known until 1782, when Goeze and later Batsch (1786) recognized under the microscope the small taenias armed with a crown of hooklets in the granulated cyst fluid. They proposed the name of *Echinococcus granulosus*. In 1821 Bremser from Vienna first reported a case of hydatid disease in a human patient who was operated upon by Kern. In 1853 Von Siebold proved that *Taenia echinococcus* was the producer of this disease. The life history of the parasite was first described by Naunyn in 1863. At the end of the past century and at the beginning of the present one Deve made a complete study of hydatidoses.

Echinococcus granulosus lives attached to the villi of the small intestine of the dog and other definitive hosts, such as wolves and foxes. When an ovum is swallowed by an intermediate host such as a pig, sheep, cow, or human the protective membrane is dissolved and the embryo penetrates the mucosa of the duodenum and the first part of the jejunum and enters the venous channels of the portal system, thus reaching the liver. Some, however, may pass through the liver and enter the inferior vena cava, thereby gaining access to other organs and tissues. The ova then forms a hydatid cyst of the liver or other viscera. Some investigators believe that the embryo may gain access to the lymphatics of the intestine, thus explaining the occurrence of hydatid cysts at sites other than the liver (Jidejian, 1957).

According to Barret and Thomas (1952) 55–60 per cent of the cysts are formed in the liver, 30 per cent in the lungs, and 2·5 per cent in the kidneys. Of the cysts at other sites, 2·5 per cent are primary cardiac cysts, 2 per cent occur in bones, 1 per cent in muscles, 0·5 per cent in the brain, and 1·5 per cent in other organs such as the spleen. Several cases of cysts of the pancreas (Anderson and Peebles, 1959) have been reported. Cysts of the omentum (Maccagno, 1955), ovary, parametrium, and pelvis (Morris, 1952), thyroid and orbit (Dew, 1928), mediastinum (Rakower and Milwidsky, 1960), and different muscles have also been observed.

Primary retroperitoneal hydatid cysts, however, are very rare while peritoneal and secondary

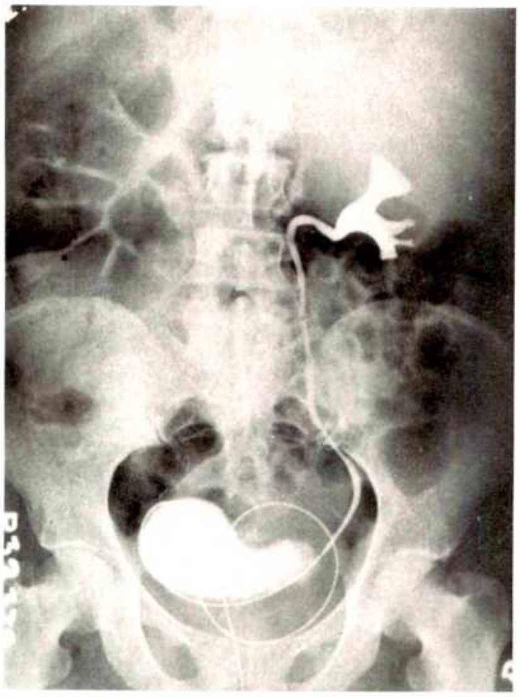

FIG. 3.—Retrograde pyelogram of the left side showing the left kidney to be pushed downwards by a mass.

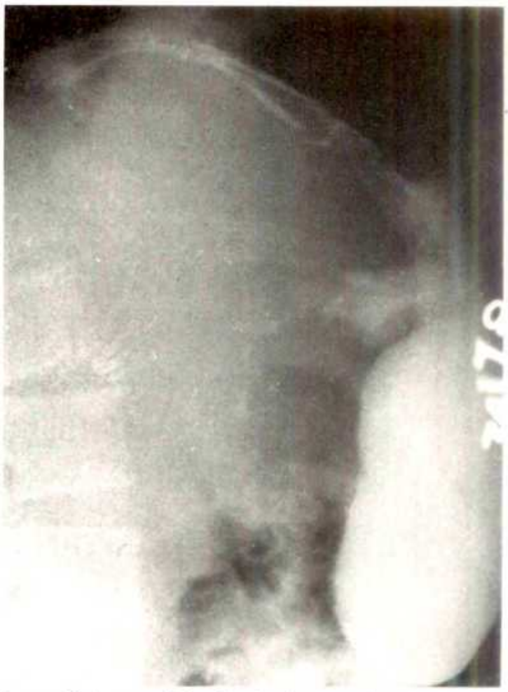

FIG. 4.—Barium-meal film showing the stomach to be displaced anteriorly by a mass.

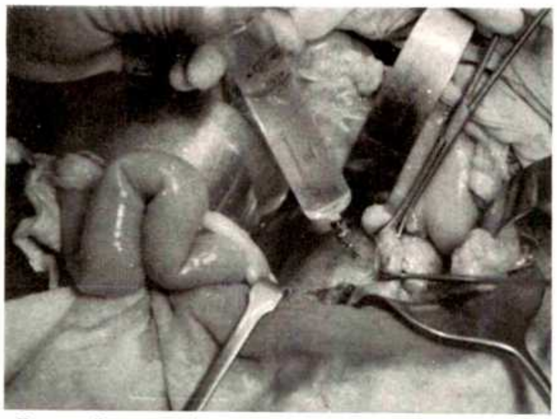

FIG. 5.—Cyst exposed at operation. Clear fluid is aspirated in the syringe.

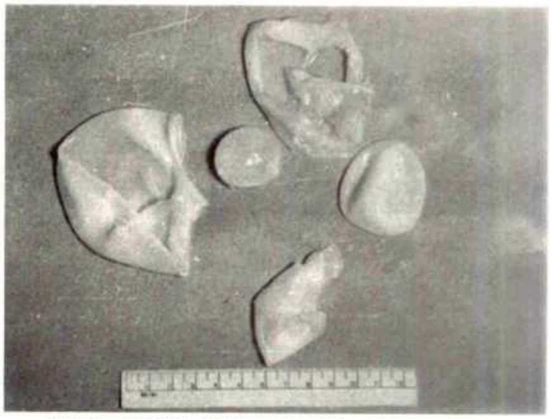

FIG. 6.—Daughter cysts evacuated from the hydatid cyst.

retroperitoneal cysts are not uncommon. Only 8 cases of primary retroperitoneal hydatid cyst have been recorded in the literature. A case of primary retroperitoneal hydatid cyst in an Indian adult is described here. Attention is drawn to the difficulty in diagnosis and management of such a lesion.

CASE REPORT

B. B., a 45-year-old woman, was admitted on 4 Aug., 1971, to Willingdon Hospital, Delhi, with a 3-month history of a lump in her abdomen. This had gradually increased in size. There was no pain, vomiting, diarrhoea, urinary complaint, fever, or loss of weight.

On examination the patient was a middle-aged female of average build. There was no anaemia, cyanosis, jaundice, oedema, or lymphadenopathy. On abdominal examination a swelling, measuring 15 × 15 cm., was felt in the left hypochondrium. The lower margin was well defined, while the upper limit could also be felt although not distinctly. The swelling did not move with respiration. It was a firm ballotable mass which was dull to percussion. The liver and spleen were not felt. There was no free fluid in the abdomen. The respiratory, cardiovascular, and central nervous systems were normal on examination.

On investigation the haemoglobin was 12 g. per cent, and the total leucocyte count was 8000 per c.mm., with polymorphs 58 per cent, lymphocytes 30 per cent, eosinophils 10 per cent, and monocytes 2 per cent. The blood-urea was 40 mg. per cent and the blood-sugar 76 mg. per cent. Albumin and sugar were absent on routine urine examination. However, on microscopic examination 10–12 pus cells and red-blood cells per c.mm were seen. Urine culture was sterile. A plain radiograph of the abdomen showed a circumscribed soft-tissue shadow in the left hypochondrium and left loin (*Fig.* 1). An intravenous pyelogram showed a non-functioning left kidney (*Fig.* 2). On a retrograde pyelogram the left-kidney pelvis was seen to be of normal calibre but the left ureter was kinked and the kidney appeared to be pushed downwards (*Fig.* 3). Barium-meal examination showed the stomach to be displaced anteriorly and to the right side (*Fig.* 4). From this it was concluded that the swelling was most probably a hydatid cyst of the spleen. Casoni's test could not be done because there was no free hydatid fluid available. A chest radiograph was normal.

An exploratory laparotomy was done via a right paramedian incision. The stomach was displaced anteriorly. The gastrocolic omentum was opened and a large cyst was found occupying the lesser sac (*Fig.* 5). The stomach and the pancreas were adherent to the anterior surface of the cyst. Clear fluid was aspirated with a syringe. Ten per cent formalin was injected into the cyst. Posteriorly the cyst was adherent to the aorta and the inferior vena cava. The splenic vessels were also adherent to it. Excision of the cyst *en masse* was not feasible in view of the dense adhesions of the cyst to major blood-vessels. The cyst was opened and fluid was aspirated. Daughter cysts were evacuated and the laminated membrane was removed (*Fig.* 6). A large Malecot catheter was left in the cyst and brought outside the skin via a separate stab incision in the left loin. The liver lobes were normal. The postoperative course was uneventful and the catheter was removed 3 weeks after operation. The patient regularly attends the follow-up clinic. She still has a sinus discharging a little fluid. A sinogram done 3 months postoperatively showed a small residual cavity. In July, 1972, when last examined the patient had no other cystic swellings.

DISCUSSION

Lockhart and Sapinza (1958), on the basis of 2 cases of hydatid cysts of the lumbar fossa and after careful study of the clinical, radiological, and operative findings, confirmed the existence of an anatomico-clinical entity of retroperitoneal hydatid cyst. Razdan, Grewal, and Rai (1963) described a case of hydatid cyst in the retroperitoneal tissues presenting clinically as an iliac abscess. Ghooi and Sikdar (1963) encountered a case of hydatid cyst arising from the sheath of the psoas major muscle and which was intimately adherent to the uterus, bladder, common iliac vessels, inferior vena cava, and lower part of the ureter. The patient succumbed to anaphylactic shock during closure of the wound. In another case of retroperitoneal hydatid cyst, described by Mathur, Bhatt, Garg, and Sharma (1969), a biopsy was taken at the first operation in the mistaken diagnosis of renal neoplasm. This patient also died of anaphylactic shock during the second operation aimed at removal of the retroperitoneal hydatid cyst.

An echinococcal cyst of the retroperitoneal cellular tissue infiltrating the inguinal and femoral areas was described by Thackuk (1967). Similar lesions of the retroperitoneal space have been described by Assonad (1964), Bernard (1965), Brardino (1969), and Uraberski (1969).

The probable mode of spread of the hydatid embryo to the retroperitoneal space is either via the lymphatics from the gastro-intestinal tract or via the portal system of the liver.

VILLOUS PAPILLOMA OF THE RECTUM (WITH UNUSUAL COMPLICATIONS)

By W. T. BERRILL

WESSEX REGIONAL RENAL UNIT, ST. MARY'S GENERAL HOSPITAL, PORTSMOUTH

SUMMARY

A case is reported in which a villous papilloma of the rectum was complicated by severe electrolyte losses and acute renal failure. Successful management by peritoneal dialysis and early surgery is described.

THE occasional complication of severe fluid and electrolyte loss from villous papillomas of the rectum is now well recognized (Hoffman, 1959; Davies, Seavey, and Sessions, 1962; Lee and Keoun, 1970). Rarely intrinsic reversible renal failure is an added complication (Kille, Blainey, Dawson-Edwards, Elkington, and Hulme, 1967).

A further such case is reported here, illustrating unusual clinical and biochemical features. The successful management by peritoneal dialysis and early resection of the tumour is described.

CASE REPORT

A 51-year-old housewife was admitted as an emergency following a 3-day history of vomiting, muscle cramps, and general malaise. On the night prior to admission her husband had helped her to the toilet no less than 20 times to pass watery mucoid fluid per rectum.

On direct questioning she had noticed recent thirst and weight-loss but initially denied any alteration in bowel habit. Later, on persistent questioning she admitted to passing two loose bowel actions a day for about 12 months previously and the occasional passage of 'water' preceding her bowel action. (She had not previously sought medical advice.)

On admission she was extremely ill and severely dehydrated with sunken facies, cold cyanosed peripheries, and clammy skin with loss of skin turgor. Her pulse was 100 per minute and thready, and her blood-pressure was 'difficult to record'. Fasciculation of the calf muscles was observed. Rectal examination revealed a rubbery frond-like tumour at 7 cm.

Immediate investigations showed a haemoglobin of 21·9 g., total protein 12·6 g., and blood-urea 320 mg. per cent (*Fig.* 1). Serum hyperviscosity made measurement of the serum electrolytes impossible.

Immediate resuscitation included intravenous infusion of 7·4 litres of normal saline (1140 mEq. of sodium), 1 litre of 5 per cent dextrose, and 220 mEq. of potassium supplements over the first 24 hours. This was followed by clinical improvement, with the supine blood-pressure rising to 120/80 and skin turgor returning towards normal. With rehydration the haemoglobin fell to 16·2 g. and the total protein to 6·4 g. She passed 625 ml. of urine. However, her blood-urea rose to 350 mg. per cent whilst the serum sodium and chloride remained extremely low (*Fig.* 1). Intravenous therapy was stopped and oral fluids were encouraged on the second day after admission.

Throughout this period the patient continued to pass rectal fluid and a further 500 ml. were released during a sigmoidoscopy which confirmed the diagnosis of villous papilloma.

Three days after admission she began to deteriorate again with vomiting, tachycardia, and signs of increasing dehydration. Only 200 ml. of urine had been passed over 24 hours and her blood-urea had risen to 400 mg. per cent whilst the serum sodium (112 mEq./l.) and chloride (80 mEq./l.) were still very low. Intravenous therapy was restarted and a further 3 litres of normal saline with 80 mEq. of potassium chloride were given. Her deterioration continued over the next 36 hours and she became confused, semi-comatose, and increasingly breathless. Clinically and radiologically she had pulmonary oedema although she appeared dry with cold peripheries and her serum sodium and chloride levels remained extremely low. The pressure in her neck veins was not elevated and there was no peripheral oedema. The blood-urea was now 470 mg. per cent with unrecordably high serum uric acid and phosphate levels. She was transferred to the Wessex Regional Renal Unit on the fifth day of admission with established acute intrinsic reversible renal failure and severe electrolyte abnormalities.

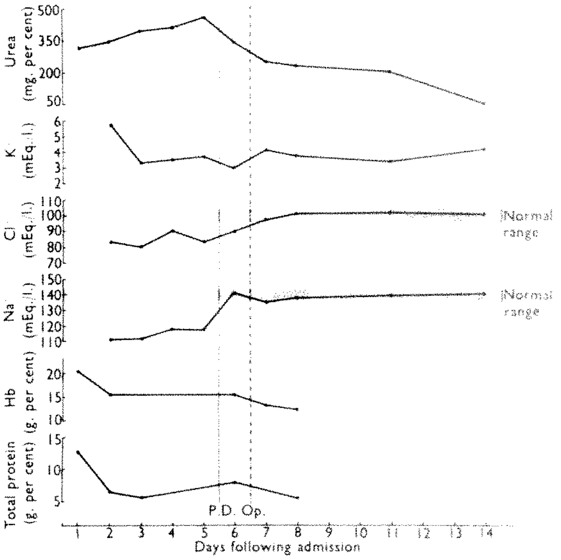

FIG. 1.—Urea, serum-electrolytes, haemoglobin, and total protein levels during the period after admission. P.D., Peritoneal dialysis. Op., Operation.

Peritoneal dialysis was immediately started. Alternating Dialaflex solutions 1·36 per cent and 6·36 per cent were given at a rate of 2 litres per hour supplemented initially by 5 mEq. and later by 7 mEq. of potassium chloride per litre. After eight exchanges a negative fluid balance was achieved with a 3-kg. weight-loss and clinical resolution of the pulmonary oedema. One litre of double-strength plasma was given to maintain serum oncotic pressure, and 300 ml. of 4·2 per cent sodium bicarbonate for correction of severe metabolic acidosis. Hydrocortisone, 10 mg. i.v., was given empirically on two occasions when unaccountable hypotension occurred. Intravenous lignocaine was given to suppress ventricular ectopics probably caused by electrolyte disturbances.

By the sixth day after admission her conscious level had improved, she was free of pulmonary oedema, her blood-pressure had risen to 140/90, and her blood-urea had fallen to 350 mg. per cent. The serum sodium had dramatically risen to 141 mEq./l. However, she remained oliguric and continued to lose enormous quantities of watery mucoid fluid per rectum (probably over a litre every 12 hours) which contained 141 mEq. of sodium per litre and 40 mEq. of potassium per litre. Control of the metabolic disturbance seemed impossible as long as the tumour remained in situ and therefore an emergency operation was decided upon. The tumour was found to be too extensive to be removed per rectum and therefore an anterior resection of the rectum was carried out. An end-to-end rectosigmoid anastomosis was carried out with temporary left iliac colostomy. The tumour measured 8 × 18 cm. and histologically there was no suggestion of malignancy.

Postoperatively the patient was given parenteral nutrition and peritoneal dialysis was continued. On the fourth postoperative day (tenth day after admission) a diuresis began and dialysis was discontinued. Thereafter, apart from thrombophlebitis of the right leg she made an uneventful recovery, renal function returning entirely to normal, and the colostomy was closed 3 months later.

Table I.—DETAILS OF CASES OF RECTAL VILLOUS PAPILLOMAS REPORTED IN THE LITERATURE

AUTHOR	AGE AND SEX OF PATIENT	PRESENTATION	BIOCHEMISTRY		DEHYDRATION PER SE OR ESTABLISHED A.I.R.R.F.*	MANAGEMENT
			Highest Blood-urea (mg. per cent)	Lowest Serum Sodium (mEq./l.)		
Fitzgerald (1955)	57 F.	Diarrhoea for 4 years	205	119	Dehydration alone	Infusion, i.v. Excision of tumour after 28 days
Jordan and Erickson (1958)	56 M.	Diarrhoea for 2 years	—	115	Dehydration alone	Intensive i.v. infusion. Abdominoperineal resection to include tumour 'at later date'
Popovsky (1965)	82 F.	Diarrhoea for 6 years	86	124	Dehydration	Infusion, i.v. Anterior resection of rectosigmoid after 15 days
Babior (1966)	69 F.	Diarrhoea for 2 months	142 (after i.v. infusion)	120	Dehydration	Infusion, i.v. Resection of tumour 'at later date'
Kille and others (1967)	56 M.	Diarrhoea for 6 years	700	112	A.I.R.R.F.	Haemodialysis. Abdominoperineal resection of rectum and tumour after 18 days
	60 M.	Diarrhoea for 4 years	560	—	? A.I.R.R.F. (inconclusive)	Haemodialysis (fluid only infused after dialysis). Resection of recto-sigmoid junction after 20 days

Lee and Keown (1970)	74 F.	Watery rectal discharge for 2 years	255	127	Dehydration	Inadequate i.v. infusion delayed until third day. Transrectal excision of tumour after 21 days
	77 M.	Diarrhoea over 'indefinite period'	475	113	Dehydration	Infusion, i.v. Transcoccygeal resection of rectal tumour after 8 days
Present series (1973)	51 F.	Acute 'watery rectal discharge' (slight looseness of bowel actions for 12 months)	470	'Unrecordable'†	A.I.R.R.F.	Intensive i.v. infusion, peritoneal dialysis, emergency laparotomy, and resection of tumour 24 hours after admission to renal unit (5 days after admission to hospital)

* A.I.R.R.F., Acute intrinsic reversible renal failure.
† After 7 litres of normal saline, 111 mEq./l.

DISCUSSION

This case illustrates a number of points. The presentation was dramatic with little preceding evidence suggesting the presence of the tumour. In almost all the previously described cases (*Table I*) acute presentation had been preceded by colitis-like symptoms lasting on average for 5 years. Popovsky (1965), in his review of the literature, stated: '*sine qua non* condition for the appearance of the "low salt syndrome" complication is a long interval (over five years) of symptoms common to villous papilloma (pseudo-diarrhoea and sero-mucoid discharge from the rectum)'.

In spite of energetic fluid and electrolyte repletion which clinically corrected the pre-renal factor the serum-sodium and chloride levels remained extremely low. Probably this continued hyponatraemia occurred because the total-body sodium was still low with perhaps relative water excess. Possibly, however, a 'sick-cell syndrome' may have developed, causing inappropriate distribution of electrolytes, the sodium pump having failed at cell-membrane level, thus allowing sodium into the cells at the expense of extracellular levels. The subsequent development of pulmonary oedema precluded further saline infusion. The pulmonary oedema may have been caused by myocardial failure due to a combination of factors such as hypokalaemia, acidosis, and hypoxia before total fluid and electrolyte repletion. Conceivably, increased permeability of pulmonary capillaries in this uraemic state (Crosbie, Snowdon, and Parsons, 1972) may have contributed.

This is the first such case reported in which peritoneal dialysis has been used, and the total correction of serum electrolytes (particularly sodium, chloride, and potassium) was rapid. Intravenous therapy alone had failed to achieve this. Peritoneal dialysis is considered a particularly safe self-regulatory method of giving potassium in an extremely precarious situation (anuric renal failure and immeasurable potassium losses).

Removal of the offending tumour was undertaken much earlier than has hitherto been customary and at a time when the patient was still clinically and biochemically unstable. It was considered that metabolic equilibrium would not have been achieved as long as the tumour, the source of the enormous electrolyte losses, remained in situ. Postoperatively the situation was relatively easy to control. Kille and others (1967) suggested that 'surgery should not be attempted until all repletion of electrolytes and fluid had been corrected', but to do this may result in such a delay that the patient perishes.

Finally, it should again be emphasized that the majority of these patients at presentation have a pre-renal uraemia secondary to the enormous fluid, protein, and electrolyte losses, especially of sodium and chloride, and will not require dialysis provided that early intensive intravenous replacement, inclusive of plasma, is given.

Acknowledgements.—I would like to thank Dr. Ralph Moore for referring this case, Mr. J. D. Younghusband for his timely surgical intervention, and Dr. Harry Lee for his supervision, advice, and permission to publish details of this case.

FAECAL FISTULA DUE TO LONG-STANDING EXTRA-UTERINE PREGNANCY

By J. W. CARSWELL AND O. EKWUEME

DEPARTMENT OF SURGERY, MAKERERE UNIVERSITY, KAMPALA

LONG-STANDING extra-uterine pregnancies are uncommon; for them to be complicated by a faecal fistula must be even more uncommon. Various causes of enterocutaneous fistula have been documented (Aird, 1957; Edmunds, Williams, and Welch, 1960), but intra-abdominal pregnancy as a cause does not appear to have been previously encountered. Two cases are presented from Mulago Hospital, Kampala, Uganda, in each of which a long-standing extra-uterine pregnancy led to the formation of a faecal fistula. In one case the small intestine and in the other the large intestine was involved.

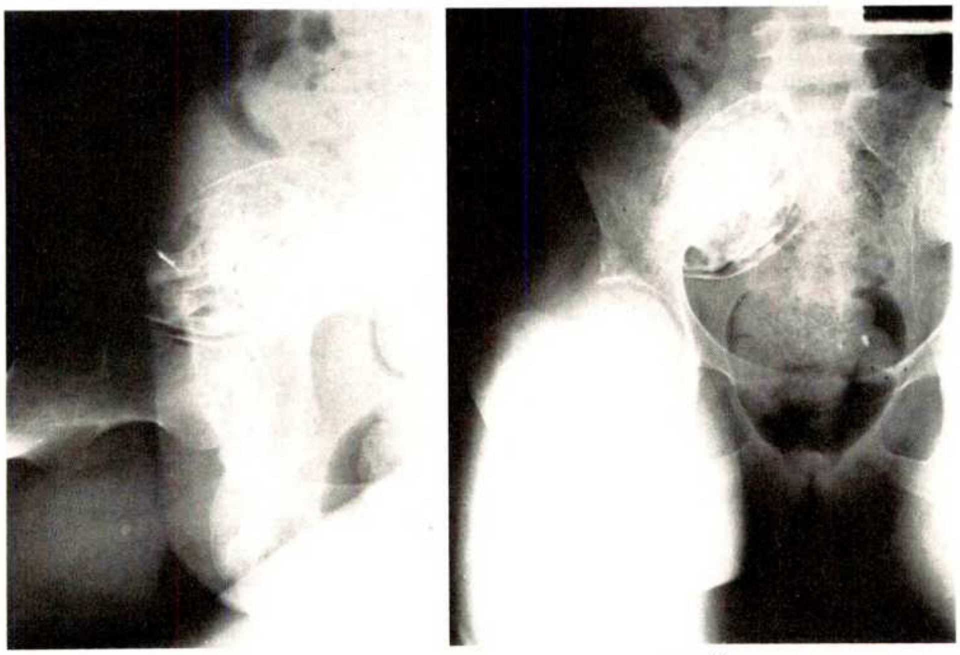
CASE REPORTS

Case 1.—The patient was a 20-year-old Luo woman from Western Kenya. She had had a normal delivery of a full-term female child in August, 1971, and had subsequently been in good health. Her periods, however, had not started again following the delivery. Just over a year later in September, 1972, she had developed a swelling in the right groin. This was painful and had gradually increased in size. The swelling had burst spontaneously 1 month later and she had started discharging faeces through the groin. She had lost weight and her general health had deteriorated.

On admission the patient was in a poor condition. She was wasted, with a haemoglobin of 10·5 g. per 100 ml. There was a fistula in her right groin just above the inguinal ligament, 4 cm. from the pubic tubercle, discharging faeces. She held her right hip in 50° flexion. A radiograph of the right iliac region showed a collection of foetal bones (*Fig.* 1).

With the help of glycerine suppositories she had normal bowel actions per rectum. After suitable preoperative preparation including sterilization of the bowel contents and blood transfusion she was operated on in November, 1972. Just under the skin in the right groin there was a cavity about as big as a clenched fist. It contained well-formed foetal bones, including skull, ribs, and long bones. The bones were removed and a formal laparotomy was carried out. There was a defect, 4 × 2·5 cm., in the antimesenteric border of the ileum about 45 cm. from the ileocaecal junction. This communicated with the cavity in the groin which also had the right ovary and tube as posterior relations (*Fig.* 2). The small gut was dissected free from the cavity. The defect in the ileum was closed transversely with two layers of catgut. The uterus and left tube appeared normal. There was no other abnormal finding and the abdomen was closed. The cavity in the groin was packed with eusol-soaked ribbon gauze. The patient made an uneventful postoperative recovery. The cavity became smaller with daily dressings and she was discharged after 4 weeks. She was seen 3 months after operation, by which time the wounds were completely healed and she had started to gain weight.

Case 2.—This patient was a 19-year-old Muganda girl. She had been well until 8 months before admission, when she had stopped menstruating and she had thought that she was pregnant for the first time. Four months later she had felt continuous central abdominal pain which had persisted in spite of treatment. She had had a scanty period about 1 month before admission. About this time she had noticed a swelling just to the right of the umbilicus.



A B

FIG. 1.—*Case* 1. Radiographs of the abdomen. A, Lateral view. B, Anteroposterior view

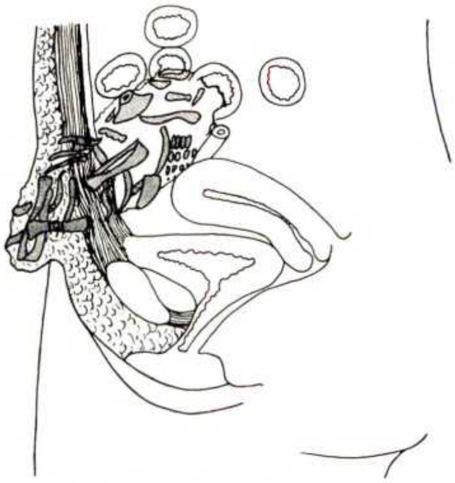


FIG. 2.—*Case* 1. Diagrammatic representation of the pathological process showing involvement of the small bowel and extrusion of foetal bones through the skin of the anterior abdominal wall.

This had subsequently burst and she had begun to discharge foul-smelling pus through the abdominal wall, 1 cm. proximal to the umbilicus in the midline.

On admission she was in good general condition. There was a slightly mobile mass 10 cm. in diameter to the right of the umbilicus and proximal to it. It was tender, smooth, and crepitant. The associated sinus discharged gas and faeculent pus. A pregnancy test was negative. Anaerobic organisms were grown from the pus in the discharging sinus. An abdominal radiograph showed a collection of foetal bones corresponding in position to the abdominal mass (*Fig.* 3).

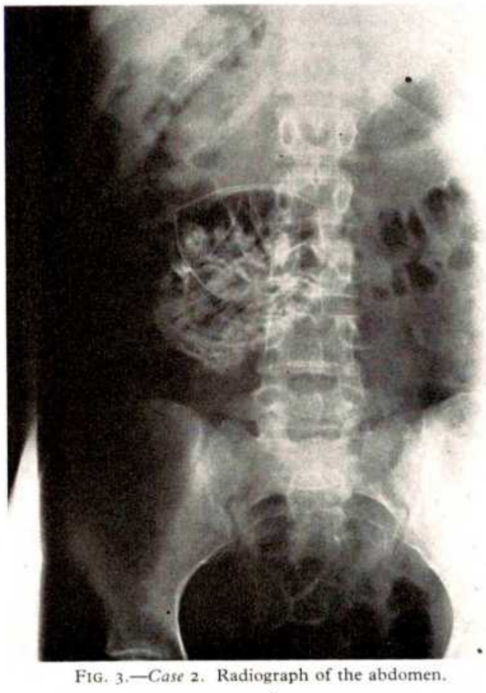

FIG. 3.—*Case* 2. Radiograph of the abdomen.

After suitable preparation including sterilization of the bowel contents she underwent operation. Laparotomy confirmed the presence of a necrotic advanced extra-uterine pregnancy. There was a marked inflammatory reaction around the foetal parts which were attached to the uterus, caecum, transverse colon, liver, gall-bladder, and anterior abdominal wall. A spicule of bone had perforated the transverse colon. The foetal parts were dissected free and the small defect in the transverse colon was closed with catgut and an omental patch. The patient made an uneventful recovery and was able to leave hospital on the ninth postoperative day.

DISCUSSION

The first recorded case of intra-abdominal pregnancy is usually attributed to Albucasis (1013–1106), the distinguished Arabian physician of Cordova. Since his time numerous references to isolated but interesting examples of extra-uterine pregnancy have been made. These historical reports have been well reviewed by Jarcho (1949) and King (1954).

Primary intraperitoneal pregnancy is extremely rare (Cavanagh, 1958) and the usual cause is an early rupture of a tubal pregnancy. Consequently a history suggestive of the accident can be obtained in many cases, as in *Case* 2. However, in *Case* 1 no such history was obtained, and the patient had had no periods since delivery 15 months previously. It is interesting to speculate when this process took place in this case. It could have occurred at the time of her pregnancy in 1971. The coexistence of an intra-uterine and extra-uterine ('combined') pregnancy is very uncommon (Novak, 1926), and the uterine pregnancy rarely goes to term (Burkhart, Mule, Begneaud, and Kohen, 1963). Alternatively, she could have become pregnant shortly after delivery in August, 1971, this pregnancy being extra-uterine.

An extra-uterine pregnancy very rarely goes to term; much more commonly foetal death occurs. The subsequent course is then variable and has been well discussed by King (1954) with illustrative examples. Frequently the gestation sac becomes infected, with suppuration and fistulation to the skin or to the neighbouring hollow viscera—vagina, bladder, or the intestines. Foetal parts may occasionally be discharged through these fistulae (Schumann, 1921). Our 2 cases are interesting in that they each presented initially with a faecal fistula and the presence of an intraperitoneal pregnancy was recognized in the course of investigation. In both cases suppuration of the gestation sac had resulted in its communication first with the intestine and later with the skin. That this is not a more common occurrence must be due to the fact that surgical interference usually takes place before this stage is reached. Douglass and Kohn (1947) and Beacham, Hernquist, Beacham, and Webster (1962) found that advanced abdominal pregnancy was more common in Negroes than in whites by sixteen and twenty times respectively. As early surgery is not always available to these patients extra-uterine pregnancy should be kept in mind as an occasional cause of enterocutaneous fistula.

REVIEWS AND NOTICES OF BOOKS

The Care of your Colostomy. By J. C. GOLIGHER, Professor of Surgery, University of Leeds, and MURIEL POLLARD, Appliance Officer, The General Infirmary at Leeds. 8 × 5 in. Pp. 31, with 41 illustrations. 1973. London: Baillière Tindall. 15p.

The Care of your Ileostomy. By J. C. GOLIGHER, Professor of Surgery, University of Leeds, and MURIEL POLLARD, Appliance Officer, The General Infirmary at Leeds. 8 × 5 in. Pp. 27, with 32 illustrations. 1973. University Department of Surgery at Leeds. 20p.

THESE two booklets have been brought up to date, the present versions being based on previous publications from the University Department of Surgery at Leeds and similar booklets published by other hospitals. They have been written to give to the patients concerned and contain sound advice about the day-to-day management of a colostomy and of an ileostomy from a practical point of view and without sentimentality. Although written for the patient to read and refer to, many surgeons will want to have copies of these books, for they contain many practical tips about which surgeons are frequently asked by their patients, and so that they can be given to their patients.

Both books provide helpful advice about day-to-day living, diet, baths, etc., and with good practical information about the many appliances now available on the British market. The names and addresses of the manufacturers and agents for the supply of these appliances are given in the appendixes. The management of many of the appliances is illustrated with clear line drawings. There is a particularly good section in the ileostomy booklet on the management of skin soreness which many surgeons and ward sisters will find invaluable.

Professor Goligher and Muriel Pollard are to be congratulated on two excellent booklets which will be a great help and solace to many patients.

Osteosynthese in der Handchirurgie. By ALFRED PANNIKE, Tübingen. 9¾ × 6½ in. Pp. 124+xi, with 167 illustrations. 1972. New York: Springer-Verlag. DM.48.

THIS book describes the use of internal fixation in relation to fractures of the bones of the hand and fingers. The previously used methods of pinning and wiring such fractures are given but the author's preference is for miniature plates and screws. The necessary surgical armamentarium is described and the different problems are well illustrated by diagrams and excellent radiographs. The author reviews over 200 such open reductions and claims results which are very much better than those using conservative means.

This volume should be of considerable interest to all surgeons involved in hand surgery and the extensive and excellent diagrams make a knowledge of German almost unnecessary in following the text.

Intensivpflege Intensivtherapie. By A. WAHLIN, L. WESTERMARK, and A. VAN DER VLIET, Stockholm; translated by H. GOERKE and edited by G. A. NEUBAUS. 9¾ × 6½ in. Pp. 223+xv. Illustrated. 1972. Berlin: Springer Verlag. DM.48.

THIS book on intensive therapy was originally published in Swedish in 1968 and has now been translated into German. It is primarily aimed at medical students, nurses, and others working in intensive-care units and is based on the experience of the intensive-care unit run by the Department of Anaesthesiology at the Karolinska Hospital. The book is full of useful advice and explains in detail but at the same time in simple terms the various procedures which may be performed in an intensive-care unit. The reasons for performing each procedure are clearly stated, and the book is well illustrated throughout by photographs and line diagrams.

An appendix lists the equipment, drugs, and infusion solutions which should be stocked in an intensive-care unit and even gives the normal values of the commoner haematological and biochemical investigations.

This is an excellent volume and could well be read with benefit by anyone involved in intensive care.

Blood Flow Measurement. Edited by COLIN ROBERTS, King's College Hospital Medical School, London. Pp. 184. Illustrated. 1972. London: Sector Publishing Ltd. £4·20.

THIS book contains 34 contributions from more than 50 authors, and comprises the bulk of the material presented at an international conference on the theory and practice of blood-flow measurement organized by the Biological Engineering Society and the Biochemical Engineering Department of King's College Hospital Medical School. It is therefore not the comprehensive manual of blood-flow methodology which the title might suggest but rather a useful guide to recent developments in some particular fields, notably the use of ultrasound and electromagnetic techniques. For those who are using or propose to use these methods, and who are familiar with their physical bases, the book will be very valuable. Nine of the chapters deal helpfully with aspects of assorted thermal and peripheral techniques.

The general medical reader will find the inevitably technical and mathematical sections leavened by chapters on the value of the measured quantities in clinical assessment.

As a contribution towards increasing, by interdisciplinary collaboration, the precision of the measurements on which clinical judgements and diagnoses are made this book is to be most warmly welcomed.

BOOK NOTICES

[*The Editorial Committee acknowledge with thanks the receipt of the following volumes. A selection will be made from these for review, precedence being given to new books and to those having the greatest interest to our readers.*]

The Anesthesiologist and the Surgeon. By JOHN P. BUNKER, M.D., Stanford, California. 8¼ × 5½ in. Pp. 158+xix. 1972. Edinburgh: Churchill Livingstone. £4.

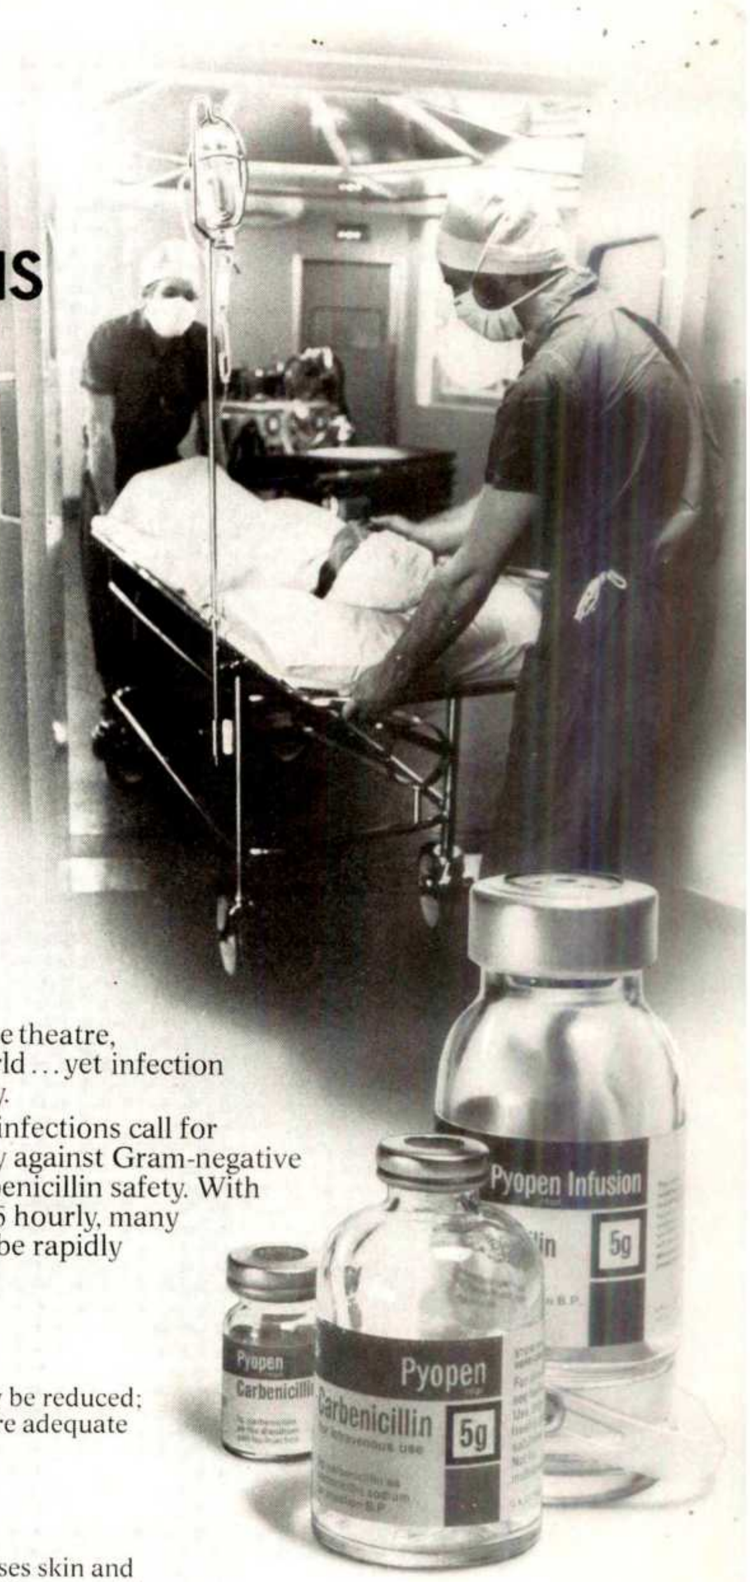
Techniques of Abortion. By SELIG NEUBARDT, M.D., F.A.C.O.G., F.A.C.S., New York, and HAROLD SCHULMAN, M.D., F.A.C.O.G., New York. 8¼ × 5½ in. Pp. 172+xi. Illustrated. 1972. Edinburgh: Churchill Livingstone. £5.

Cardiac Surgery. Edited by JOHN C. NORMAN, M.D. Boston. 9½ × 6½ in. Pp. 703+vii. Illustrated. 1972. New York: Appleton-Century-Crofts. $18.95.

Manual of Fracture and Orthopaedic Surgery. By K. S. BOSE, M.S. (Cal.), F.A.M.S., Calcutta. 8½ × 5½ in. Pp. 262+xii. Illustrated. 1972. Calcutta: Kamala Books. Price not given.

Metabolic, Degenerative, and Inflammatory Diseases of Bones and Joints. By HENRY L. JAFFE, M.D., New York. 10 × 7 in. Pp. 1101+xi, with 1066 illustrations. 1972. London: Henry Kimpton. £15·75.

Angiography of Trauma. By WHEI-RUNG FU, M.D. Washington. 9 × 6 in. Pp. 106+vii, with 32 illustrations. 1972. Springfield, Ill.: Charles C. Thomas. $11.75.



When pseudomonas threatens the success of surgery

Pyopen

The skill of the surgical team, hours in the theatre, the most advanced techniques in the world . . . yet infection can still throw the outcome into jeopardy.

Post-operative pseudomonas or proteus infections call for Pyopen. Only Pyopen offers good activity against Gram-negative organisms with the added advantage of penicillin safety. With intravenous Pyopen, at a dosage of 5g 4-6 hourly, many dangerous post-operative infections can be rapidly controlled.

Adult Dosage
5g I.V. 4-6 hourly.
In patients with renal impairment dosage may be reduced; monitoring is advisable in these cases to ensure adequate serum antibiotic levels.

Contra-indication
Penicillin hypersensitivity.

Side-effects
As with other injectable penicillins. In rare cases skin and mucous membrane haemorrhages due to interference with normal clotting mechanisms have been reported.

Pyopen–by infusion or injection

Further information is available on request.
Pyopen* (carbenicillin sodium B.P.) is a British product originated by
Beecham Research Laboratories, Brentford, England.

RADIOTOM 619

for surgical diathermy

The *RADIOTOM 619 is a universal electrosurgical apparatus designed to meet all the clinical requirements of general surgery and the special requirements of neurosurgery.

The RADIOTOM 619 can be placed on a trolley. The small dimensions and the low weight of the unit also make it possible to mount it in a ceiling column, build it into a wall or to use it on a wall bracket or a floor column.

Recent Publications

Spratt *et al.*:

EXENTERATIVE SURGERY OF THE PELVIS

(Major Problems in Clinical Surgery XII)

This is a new volume dealing exclusively with advanced pelvic neoplasms requiring exenterative surgery. It provides a systematic organisation of surgical techniques and instrumentation, pelvic pathology, pelvic anatomy, pre- and postoperative care, psychological and social problems unique to the operations and rehabilitation.

By John S. Spratt, Jr., MD, *University of Missouri, Columbia*; Harvey R. Butcher, Jr., MD, *Washington University School of Medicine*; and Eugene M. Bricker, MD, *Washington University School of Medicine.*

177 pages. Illustrated. April 1973. £3·75.

Rees & Wood-Smith:

COSMETIC FACIAL SURGERY

A comprehensively detailed clinical text and a useful reference atlas, this volume will prove to be of invaluable assistance to the learning cosmetic surgeon as well as to the experienced practitioner. It is advanced, authoritative and complete. Special chapters are included on the latest advances in dermabrasion, chemical face peeling, and hair transplantation.

By Thomas D. Rees, MD, FACS, *Associate Clinical Professor of Surgery* (*Plastic*); and Donald Wood-Smith, MD, FACS, *Assistant Clinical Professor of Surgery* (*Plastic*), both of the *New York University Medical School, New York.*

609 pages. Over 1500 illustrations (35 in colour). February 1973. £23·40.

Forthcoming Titles

Chase:

ATLAS OF HAND SURGERY

A deluxe atlas made up of 95 individual "lessons" grouped under ten major headings and covering the entire field of hand surgery. Large operative drawings are placed within the text, exactly where the discussion refers to them, so that there are no separate legends. Each lesson consists of a surgical principle and a case example, with sometimes a further discussion and most of the time a set of preoperative and postoperative photographs.

By Robert A. Chase, MD, *Stanford University School of Medicine.*

About 375 pages. Illustrated. About November 1973. Approximately £14·90.

Linton:

ATLAS OF VASCULAR SURGERY

This atlas, amply illustrated with carefully executed colour drawings, describes in detail operative procedures that have been found most satisfactory for treatment of more common peripheral vascular diseases.

By Robert L. Linton, *Brookline, Massachusetts.*

About 500 pages. About 230 illustrations. About December 1973. Approx. £21·25.

EYE SURGERY. 5th Edition

H. B. Stallard, M.B.E., T.D., M.A., M.D. (CANTAB.), M.CHIR., F.R.C.S. (ENG.), HON.LL.D. (ST. ANDREWS), *Surgeon, Moorfields Eye Hospital; Eye Surgeon, St. Bartholomew's Hospital.*

This new and completely re-designed edition covers the whole field of eye surgery including orbital and reconstructive (plastic) surgery. Complete updating of material with an individual selective approach to operative procedures rather than a general survey of the possible techniques makes this the authoritative work for all eye surgeons. Postgraduates will find it fully covers their needs. As a reference book it should be in every library.

946 pages 779 illustrations **£13·25**

A MANUAL OF ANAESTHETIC TECHNIQUES. 4th Edition

W. J. Pryor, M.B., CH.B. (N.Z.), F.F.A. R.C.S. (ENG.), D.A. (ENG.), F.F.A. R.A.C.S., *Anaesthetist, Christchurch Hospital, New Zealand,* and D. C. T. Bush, V.R.C., M.B., CH.B. (N.Z.), D.A. (ENG.), F.F.A. R.A.C.S., *Anaesthetist, Christchurch Hospital, New Zealand.*

Amongst the new sections added to this completely revised edition are neurolept-analgesia and dissociative anaesthesia. This should be of great interest to house surgeons, anaesthetic registrars, and those in need of specialized information.

424 pages 123 illustrations **approx. £7·00**

COMMON SURGICAL EMERGENCIES

C. B. Williams, M.D., F.R.C.S., *Senior Registrar in General Surgery, United Bristol Hospitals.*

This book is designed to provide the information needed for the 'on the spot' management of surgical emergencies. It also includes a list of drugs in common use under these conditions.

156 pages Illustrated **£1·50**

. . . but what happens in the patient's legs?

"The venous return seems to be carried through a few transport vessels during operation, while the majority of the veins of the calf appear to be excluded from participation in venous return. This exclusion from venous flow in the legs was considered to be a main factor in the establishment of postoperative thrombosis.

Infusion of 500 ml 10% dextran 40* during general anaesthesia and abdominal surgery maintained or restored preoperative flow pattern in the venous system of the lower extremities.

The thrombosis protecting effect of dextran found in this study together with the effect of dextran 40 on venous flow reemphasizes the importance of flow improvement for the prophylaxis of postoperative thromboembolism."

When Agnes Foster was stitched with a non-absorbable suture it meant a return to Out-Patients for stitch removal – more work for the busy Casualty staff and another worrying journey for an old lady. This could have been avoided with Dexon* sutures.

Dexon* sutures are absorbable so that, in many cases, particularly with subcuticular stitches, patients need not come back for stitch removal – a procedure which some, particularly the old, may regard with fear and apprehension.

Dexon*

The everybody benefits suture

An extra 16p per 300 pages will be charged for reprints sent to outside the United Kingdom.

An additional charge will be made for reprints containing coloured illustrations, depending upon the amount of extra work involved.

Business Communications should be addressed to *John Wright & Sons Ltd., British Journal of Surgery, Bristol, BS8 1EX.* Remittances should be made payable to *The British Journal of Surgery.*

Binding.—Handsome Cloth Cases may be obtained for binding Vol. 59. Case 70p post free; Case and binding £2·75, post free. Cases are also available for some of the earlier volumes. Applications should be made to the Publishers, who will also undertake the binding if desired.

Back Numbers.—The Publishers would be glad to purchase copies in good condition of Nos. 1, 3, and 8, Vol. 51; No. 9, Vol. 53; No. 10, Vol. 54; and Nos. 11 and 12, Vol. 55.

Advertisements.—All communications should be addressed to *H. S. Janes & Partners (Publications) Ltd., St Martin's House, 159 Clapham High Street, London, SW4 7SU* (telephone 01-622 9225).

INSTRUCTIONS TO AUTHORS

Preparation of MS.—Papers should be submitted in typescript and the author should retain a carbon copy. Double spacing should be used throughout, except for quotations.

Tables and Illustrations.—Tables should be numbered in roman numerals and set out on sheets separate from the text. Illustrations, too, should be kept separate from the text and should be numbered consecutively in arabic numerals. Each figure should be referred to in the text, and the descriptive legends should be typewritten on a separate sheet of paper, and not put on the backs of the originals. Glossy photographs should be supplied unmounted and positive prints (not X-ray films or lantern slides), also unmounted, should be sent whenever possible. Drawings should be in a finished state suitable for reproduction. When *coloured illustrations* are submitted as colour prints they should be accompanied by the actual transparencies where possible. As coloured illustrations are very expensive to reproduce, the author may on occasion be asked to make a contribution towards the cost.

REFERENCES

Attention is drawn to the Advance Notice of the Change of Instructions for Authors on the loose insert in this number of the Journal.

SEPTRIN TACTICS

first

SEPTRIN ensures coverage against all likely bacterial pathogens.

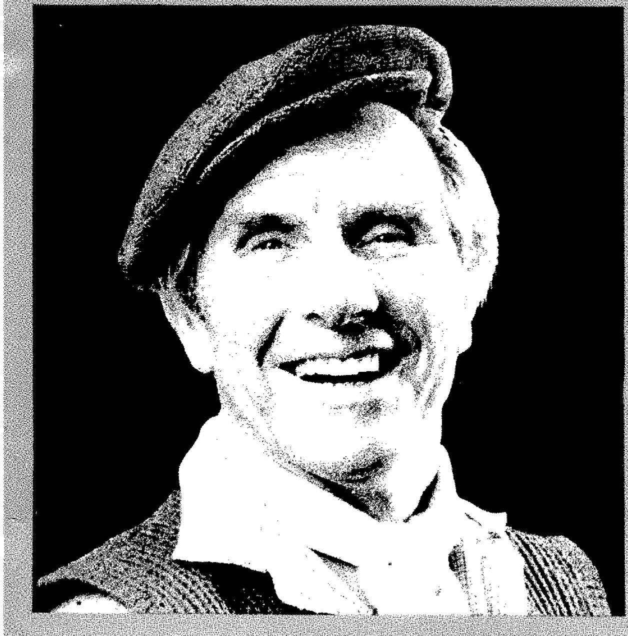
fast

SEPTRIN rapidly obtains effective blood levels with simple twice daily dosage.

decisive

SEPTRIN crushes bacterial resistance with a bactericidal action which differs essentially from that of other antibacterials.

they've proved superior in bronchitis



Superior to either ampicillin or tetracycline as judged by reduction in sputum purulence or sputum volume.[1,2]

"...not only are the two primary pathogens, *Strep pneumoniae* and *H influenzae*, sensitive, but so are the secondary invaders such as klebsiella which often replace them after antibiotic treatment."[3]

"...can only be considered excellent on the criteria originally specified, namely the elimination of the infecting micro-organism."[4]

CHARLES C THOMAS • PUBLISHER

SURGICAL ANATOMY FOR CLINICAL EXAMINATION *by* **Andrew M. Munster,** *Medical Univ. of South Carolina, and* **George J. Thomas,** *Brooke General Hospital, Fort Sam Houston, Texas.* This text bridges the gap between the voluminous amount of anatomy which used to be taught and which there is no longer time to learn, and the basic, essential anatomic facts which must be retained. It is essentially an outline of regional anatomy with a heavy emphasis on practical clinical examination. Problem areas are extensively detailed. The clinical experience of the authors is used in discussions on abnormal masses in certain areas. Actual techniques of physical examination are detailed for the oral cavity, the breast, various joints, and the female pelvis. *'73, 144 pp. (7 x 10), 100 il., $10.75*

CRYOSURGERY OF TUMORS OF THE SKIN AND ORAL CAVITY *by* **Setrag A. Zacarian,** *Boston Univ. School of Medicine, Massachusetts. Forewords by* **John G. Bellows** *and* **Ervin Epstein.** The result of over eight years experience in cryosurgery of 1720 malignant tumors of the skin in 920 patients, this monograph details a method of surgery which may soon offer the effective, anesthetic destruction of unwanted tissues, hemostasis, and controlled delimitation along with remarkable wound healing. Its purpose is twofold: first, to familiarize the physician with the fundamentals of cryogenesis; and second to acquaint the surgeon with the technique of cryosurgery and its indications for the management of external neoplasms and neoplasms of the oral cavity. *'73, about 301 pp. (6 3/4 x 9 3/4), 268 il. (28 in full color), 18 tables*

PLASTICS MATERIALS IN SURGERY (2nd Ed.) *by* **Bernard Bloch,** *Sydney Hospital, Sydney, Australia, and* **Garth W. Hastings,** *North Staffordshire Polytechnic, Stoke-on-Trent, England.* This completely revised and rewritten Second Edition presents new critical and factual analysis of current applications. An up-dated reveiw of every material in current use is covered. Major applications and pitfalls are clearly described. A new chapter on the sterilization of these materials is presented with an outline of physical and toxicological tests required in the assessment of plastics implant material . . . the reaction of living tissues to various implant materials is explored. Problems of degradation, wear and toxicity of implants are detailed. *'72, 284 pp., 9 il., 4 tables, $18.75*

SURGERY OF THE ANUS, RECTUM AND COLON (2nd Ed., 3rd Ptg.) *by* **J. C. Goligher,** *Univ. of Leeds, Yorks, England. With the Collaboration of* **H. L. Duthie** *and* **H. H. Nixon.** While thoroughly representing the literature on the subject, it strongly reflects the authors' vast personal experience and considered views. Very extensive revisions have been necessary throughout the text to incorporate the experience gained in surgical procedures since publication of the First Edition. NEW MATERIAL HAS BEEN ADDED on benign juvenile polyps, the Peutz-Jegher's syndrome, and metaplastic polyps. The chapters on malignancy have been considerably altered, and new sections added throughout on diagnosis, treatment, and postoperative care. *'72, 950 pp. (7 1/2 x 10), 654 il. (30 in full color), $39.75*

APPLIED SURGICAL ANATOMY *by* **Charles Marks,** *Charity Hospital, New Orleans, Louisiana. Foreword by* **William D. Holden.** For the successful application of operative surgery . . . a comprehensive and practical text reviewing fundamental aspects of anatomy and relating these facts to clinical situations and overall medical relevance. By use of this text, the beginning medical student will see more clearly in the integration of anatomic facts in clinical and radiologic investigation, and will learn to appreciate the relevance of normal anatomy and its interrelationship to disturbed function. The illustrative materials include not only anatomic representations, but also x-ray photographs and examples of pathologic material. *'72, 608 pp., 151 il. (16 in full color), $22.50*

FINANCIAL ADVICE FOR PHYSICIANS *by* **John N. Sheagren.** *Foreword by* **Norman F. Dacey.** Each unique financial problem of the physician is outlined. The medical student and house officer will particularly benefit from the descriptions of life insurance and the best type to purchase; other types of insurance coverages and how they represent the reserve for contingency; investments – which are best and how to get started; basic principles of estate planning and a sketch of a reasonable life-long plan for the average physician. The established physician will find much value in discussions of investment media and investing techniques; wills, trusts, and the problem of probate; and taxes – death, gift and income. *'72, 132 pp., 1 table, $7.75*

SURGERY AND THE ALLERGIC PATIENT *edited by* **Claude A. Frazier,** *Asheville, North Carolina. Forewords by* **Warren H. Cole** *and* **L. Nelson Bell.** *(12 Contributors)* One of the first texts devoted to full coverage of surgery and allergy . . . can be used as a quick reference in the hospital emergency room or operating room. Covers management of anaphylaxis, the pediatric and adult patient – correct dosages for allergy medications, preoperative pulmonary function evaluation, preoperative and postoperative medical management, management of dermatological problems in surgery, management of surgical complications of asthma in children and adults, drug reactions, ENT surgery and allergy. *'71, 212 pp. (6 3/4 x 9 3/4), 44 il. (7 in full color), 8 tables, $12 50*

STEREOTAXIS AND RADIOSURGERY: An Operative System *by* **Lars Leksell,** *Karolinska Institutet, Stockholm, Sweden.* Cerebral radiosurgery as a clinical method has now become established and the stereotaxic procedures may be subdivided into open operations using electrodes or other instruments, and closed radiosurgery by means of x-rays or other types of radiant energy. This monograph describes an integrated system for performing open stereotaxic operations with radiofrequency heat lesions and for closed intracranial radiosurgery using high energy gamma rays. Summarizes from a technical viewpoint the result of many years inquiry into the potentialities of stereotaxic brain surgery. *'71, 84 pp. (6 3/4 x 9 3/4), 67 il., $7.75*

Basic Clinical Surgery for Nurses and Medical Students

Edited by John McFarland, MD, ChM, FRCS

Designed to help all those students, whether of nursing or of medicine, who are starting work in surgical wards. The first chapters contain a basic introduction to the principles of general surgery and the management of trauma, while the later chapters deal with each branch of surgery systematically, emphasis being laid on the practical management of the surgical patient.
1973 500 pp. illustrated 0 407 80100 6 £2·50

Bone—Certain Aspects of Neoplasia

Colston Papers No. 24

Editors: C. H. G. Price, MD, FRCPath
F. G. M. Ross, BA, MB, BCh, BAO(Dublin), DMRD, FFR(Lond. & Dublin)

Consists of 37 original papers dealing with current problems of diagnosis and treatment of osteosarcoma, Paget's sarcoma, fibrosarcoma, chondrosarcoma, reticulosarcoma, Ewing's tumour, and giant cell tumour. Many controversial points of tumour diagnosis, behaviour and therapy are discussed in the light of the experience of workers from many countries.
1973 500 pp. illustrated 0 407 70530 2 £12·00

Clinical Cardiac Radiology

Keith Jefferson, MA, FCRP, FFR
Simon Rees, MA, MRCP, FFR

This is a practical book on the use of chest X-ray in heart disease, written for radiologists, physicians and surgeons. It is based on a study of films from over 1,500 patients in whom the anatomy of the heart and the physiology of the circulation were known, with computer analysis used where appropriate. The significance of the radiological signs is evaluated in light of these findings.
1973 326 pp. illustrated 0 407 13575 8 £15·00

Heart Disease in Paediatrics

S. C. Jordan MD, MRCP
Olive Scott MD, FRCP

Essentially practical in approach, this book provides well illustrated and up-to-date information on methods of diagnosis and treatment, particularly of congenital heart disease. It shows to what extent the clinical signs and symptoms—assisted by radiology and electrocardiography—can indicate the diagnosis, and when further investigation will be required. Also presented is a scheme to simplify diagnosis of heart disease in the newborn infant. A title in the *Postgraduate Paediatrics* Series.
1973 304 pp. illustrated 0 407 19940 3 £5·25

Modern Trends in Oncology—1

Edited by Ronald W. Raven, OBE(Mil), OStJ, TD, FRCS

Volume I, *Research Progress*, focusses attention on the developing areas and future trends in oncological research. Various aspects of the world-wide aetiological, immunological and carcinogenic research work are clearly documented.
Volume II, *Clinical Progress*, concentrates on detection and screening techniques, and draws attention to the methods now available for the control and treatment of cancer. Considerable emphasis is placed on community problems and on the care and well-being of the cancer patient.
Volume I: 1973 296 pp. illustrated 0 407 30580 7 £7·00
Volume II: 1973 332 pp. illustrated 0 407 30581 5 £7·00

Emergency Abdominal Surgery
in Infancy, Childhood and Adult Life

Peter F. Jones M.CHIR. F.R.C.S. F.R.C.S.E. January 1974. 600 pages, 150 illustrations. About £10·00

This book has been written for the surgical trainee as a practical day-to-day companion and for the practising surgeon working in isolation who needs to reconsider an unfamiliar subject. The chapters review the major abdominal visceral emergencies—the acute abdomen in infancy and childhood, acute appendicitis, intestinal obstruction, acute gastro-duodenal haemorrhage and perforation, inflammatory diseases of the intestines, pancreas and gall bladder, the acute abdomen in pregnancy, urological emergencies and abdominal injuries.

The Surgery of the Central Nervous System
a Textbook for Postgraduate Students

D. W. C. Northfield M.S. F.R.C.S. F.R.C.P. 1973. 896 pages, 240 illustrations (15 colour). £22·50

The aim of this book is to provide a guide for the postgraduate who is starting his specialised training in neurological surgery. It discusses the physiology and pathology of the intracranial pressure—normal and increased, of the cerebrospinal fluid and the cerebral circulation. Emphasis is placed upon clinical manifestations: pathology, diagnosis, choice of treatment and the results of operations are included.

Complications in Vascular Surgery

Edited by Hugh G. Beebe M.D. 1973. 402 pages, 175 illustrations. Lippincott, £14·00

Vascular surgery has made spectacular advances during the last two decades, and this book has been designed to present an authoritative appraisal of what has been achieved and how newly developed techniques should be utilized for the best management of complications.

Management of the Patient for Radical Cancer Surgery

[redacted] by William S. Howland M.D. and Olga Schweizer M.D. 1973. 176 pages, 40 illustrations. Davis, £5·00

This new title in the *Clinical Anaesthesia* series concentrates on those matters which have a direct effect on the success or failure of the anaesthesia and operation.

First and for all.

In severe neo-natal infections

In septicaemias

In serious post-operative situations

G-DAY-those first vital 24 hours in serious bacterial infections:

- when effective therapy must be initiated to prevent rapid deterioration in the patient's condition
- when the causative organism is unknown or uncertain
- when there is no time for trial and error

When these situations occur in acute or acute on chronic infections, Genticin Injectable, the antibiotic with the broadest bactericidal spectrum of all, has proved eminently successful as first-line therapy in a wide range of conditions.

"It therefore follows that on sensitivity testing alone, gentamicin (Genticin) would be the best single antibiotic for blind chemotherapy."[1]

[1]Reference: J Irish med Ass, 65, No 20, 514, 1972.

Genticin Injectable is available in 2 ml multidose vials and snap-off ampoules. Each 2 ml contains 80 mg gentamicin base as gentamicin sulphate.

Further details are available on request from:

Sit down with Sierex

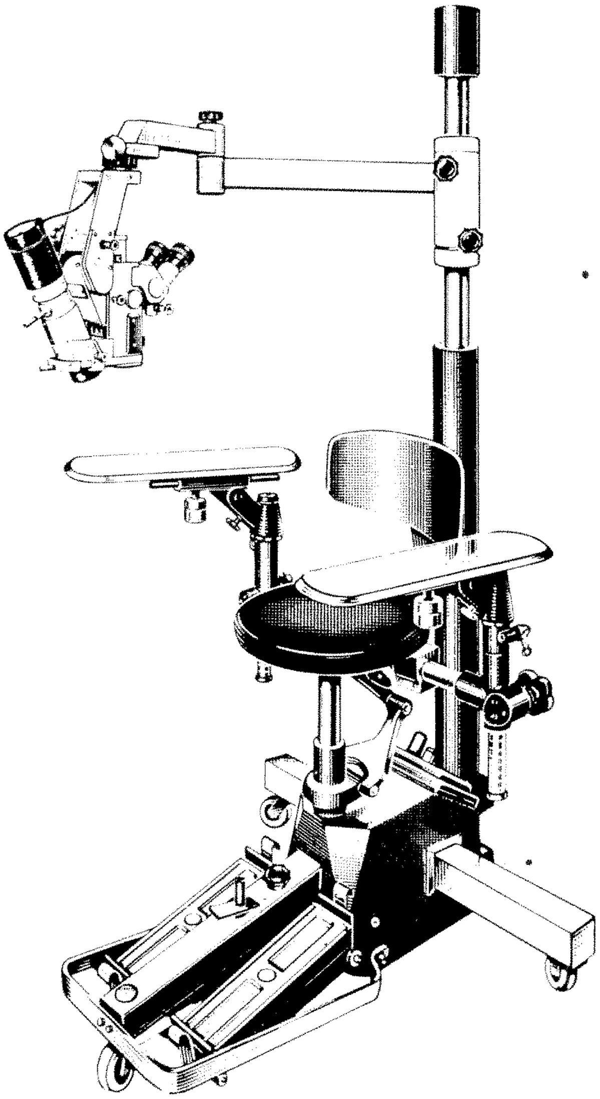
The Möller Chair avoids the necessity and expense of permanent ceiling-mounted equipment. Connected to a control box mounted on a wall arm or ceiling pendant, there are no cables to trail across the floor; greater mobility for the chair to move around the table.

The microscope is of the split-beam type and has co-axial and, alternatively, inclined illumination. The zoom gives a magnification from 5X to 25X.

The assistant's microscope can be attached to either side of the surgeon's microscope and its position is such that he can approach the operating field from under the surgeon's hands.

Still, cine and TV cameras can be attached to the microscope and the whole chair can be wheeled from one theatre to another.

Using the foot switches the surgeon can alter the position of the seat, adjust the magnification of the microscope, activate surgical diathermy and cryosurgical units etc.



The use of microsurgical techniques is increasing, with applications in Neuro, ENT, Plastic and Ophthalmic surgery.

Designed for micro-surgical procedures, this Möller-Wedel equipment, introduced to the U.K. by Sierex Ltd., comprises a motorised surgeon's chair and Möller microscope. Footswitches control the height of the chair, raise and lower the microscope, adjust the magnification, activate surgical diathermy and cryo-surgical units, operate still, cine and television cameras . . . and control the operating table too.

Sierex will be pleased to tell you all about it.

THE
BRITISH JOURNAL OF SURGERY

Vol. 60 DECEMBER, 1973 No. 12

EDITORIAL

As we stand at the threshold of 1974 with all its portents for the Health Services of Great Britain, we would wish our readers to know about changes that are being introduced with the January number of the BRITISH JOURNAL OF SURGERY. Since it first appeared in July 1913 there have been only three changes of format, and the Editorial Committee has decided that the time has come to introduce a number of changes in style and lay-out. In future every article will begin on a new page. This we hope will improve the appearance of the Journal, as well as making it easier to present a more attractive reprint production. Spare space will be used, where appropriate, for short items of selected material of topical, historical, or philosophical interest; the Editorial Committee hopes that readers will contribute items for this purpose, and their help will be welcome.

Volume 61 will differ from the present one in several other ways. The names of the authors of an article will alternate with the title of the article at the top of each page. The full journal reference will appear at the beginning of each article. This should help with the identification of reprints and photocopies. Authors will have their appointments at the time of submitting their article printed as a footnote on the first page. There will be important alterations in the citation of references; these are explained in the Changes to Instructions to Authors, which have already been distributed as loose inserts in recent numbers of the Journal.

Headings will be clearer and the lay-out of tables will be 'cleaner'. The type face will in future be Times for the text material and Grotesque bold for the article headings instead of the present Plantin. The portrait of Lister will return to the cover, which itself has been completely redesigned.

It has been decided to publish in the Journal a limited number of review articles; some of these will be by invitation, but if authors wish to submit articles of this nature they will be welcome and will be considered by the Editorial Committee in the usual manner. Book reviews will appear over the name of the reviewer and it is intended in future to list those of less particular value to our readers. Obituary notices will be limited to those who have made outstanding contributions to surgery. Rare cases will no longer be accepted unless they are of exceptional interest or importance. In future all articles should be sent to the Editorial Secretary at the Bristol address.

We are grateful to our Publishers for their willing and enthusiastic co-operation in the redesign of the Journal and with them we share the hope that the changes now due to take place may be acceptable to our readers and will improve the value of the work in future issues.

H. H. G. EASTCOTT
Editorial Secretary

ORIGINAL PAPERS

A HYPOTHESIS ON SOME FACTORS GOVERNING THE BEHAVIOUR OF SHORT SEGMENTS OF THE SMALL BOWEL

By D. H. R. JENKINS*

DEPARTMENT OF CLINICAL SURGERY, UNIVERSITY OF EDINBURGH

SUMMARY

A hypothesis is advanced in which it is argued that variations in the extrinsic autonomic innervation of short small-bowel segments are responsible for the unpredictable behaviour of such segments. Experimental evidence is offered to substantiate the hypothesis.

THE use of reversed intestinal segments in the treatment of the short-bowel syndrome is well established, but the optimum length of the segment is yet to be determined. Reports of both experimental work (Singleton, 1954; Hammer, Seay, and Johnson, 1959; Baldwin-Price and Singleton, 1965) and actual application of antiperistaltic segments in the control of the short-bowel syndrome in the human (Gibson and Blackman, 1962; Sako and Blackman, 1962; Ellis and Coll, 1968) have been made. It is accepted that the resection of more than three-quarters of the small bowel will lead to weight-loss, hypoproteinaemia, steatorrhoea, and malabsorption (Jenesius, 1945; Jackson, 1958; Ellis and Coll, 1968). Antiperistaltic segments will produce incomplete intestinal obstruction with delay in intestinal transit time and retention of carbohydrate and protein, and to a lesser extent fat, leading to their greater absorption and they thus reverse, in part at least, the effect of the loss of a large percentage of the small bowel (Shepherd, 1966).

By trial and error it has been established that a 7·5–10-cm. segment of terminal ileum interposed in an antiperistaltic manner in the human will significantly delay intestinal transit time (Editorial, 1971).

Not only does the optimum length of reversed segment need to be established, but also the site from which such a segment should be taken. Furthermore, an understanding of the mechanism involved in the behaviour of such segments is required if a rational approach, based on physiological reasoning, is to be adopted. Review of the literature has revealed that there is little to suggest that such mechanisms have been fully examined.

Torbey (1960) and Torbey and Waddell (1961) noted that some short segments of the ileum supplied by one vascular pedicle exhibited a high degree of tone and remained contracted after isolation from the gut. This finding has been confirmed in rabbits (Jenkins and Macleod, 1970), and later work in rabbits and dogs by the same authors (Jenkins and Macleod, 1972) indicated mechanisms which might be involved. As a result of their experiments Jenkins and Macleod suggested that the vagus was uniformly distributed to the whole of the small bowel, serving to maintain tone. On the other hand, the jejunum had no extrinsic sympathetic supply and the ileum had one distributed in an irregular manner only. The suggestion was made that when there was both a sympathetic and a parasympathetic component, reaching the segment in question via the main branches of the superior mesenteric artery, a regular and predictable response could be expected from such a segment placed in either an iso- or an antiperistaltic manner. When a high degree of tone was noted in a short segment of distal ileum this was thought to be due to the uninhibited effect of the vagus on that particular segment. From the results it was argued that the variations in the extrinsic autonomic supply were responsible for the peculiarities in behaviour observed.

If these suggestions are correct they clearly have relevance to the question of the selection of a segment for reversal in the treatment of the short-bowel syndrome.

In order to test the hypothesis outlined, experiments were performed on dogs in which a prediction was made of the behaviour of a particular segment of distal ileum following its isolation but before its insertion in continuity with the gut. If the predicted behaviour could be shown to occur then rules could be established from the physiological and anatomical basis of variation in the extrinsic autonomic supply governing the selection of segments of the small bowel for their use in a therapeutic situation.

MATERIALS AND METHODS

In 6 adult mongrel dogs, weighing between 10·0 and 14·5 kg., the abdomen was opened by a midline incision. The ileum was identified and an estimate was made of its length. A segment of distal ileum, 10 cm. from the ileocaecal junction, supplied by one or by two vessels and 10 cm. in length was selected and marked with fine silk sutures. The distal half of the remainder of the ileum was excised. The selected 10-cm. segment was anastomosed in continuity with the remaining bowel in either an anti- or isoperistaltic manner. Single-layer interrupted 000 Dexon sutures were used with the suture line everted in all cases.

---

* Present address: University Hospital of Wales, Cardiff.

The defects in the mesentery were closed and the abdomen was re-sutured in layers. In 2 other dogs 20-cm. lengths of distal ileum were selected and reanastomosed in the manner described. Both were supplied by two vessels.

Initially the dogs were drip fed with a glucose/saline solution but when they were fully conscious and ambulant they were given food of a standard proprietary brand. All the dogs, irrespective of weight, received ample food in excess of the manufacturer's recommendations. The dogs were weighed frequently. The intestinal transit time was assessed by observing the mouth-to-anus time of methylene blue. Post-mortem examinations were performed on all the animals.

RESULTS

In dogs II, V, and VI (*Table I*) the single-vessel distal ileal segment contracted visibly following isolation and it was anticipated that some degree of obstruction would result following interposition of such segments. Dog II (antiperistaltic interposition) and dog V (isoperistaltic interposition) gained weight before death and dog II remained well for 83 days. Dog V was put down on day 20 when clinical signs of intestinal obstruction developed which was confirmed at autopsy. Obstruction also occurred at the site of the interposed segment in dog VI and he was put down on day 8, having lost 0·4 kg. in weight.

In dogs I, III, and VIII double-vessel segments were interposed in an isoperistaltic manner. It was anticipated that there would be no obstruction due to the interposed segments and that weight-loss would ensue. Weight-loss was seen in all 3 dogs and led to dog VIII being killed at an early date.

In dogs IV and VII double-vessel segments were interposed in an antiperistaltic manner and a large weight-loss was predicted and was, in fact, observed.

Intestinal transit times, measured by an admittedly crude method, were increased in the dogs in which single-vessel segments had been interposed.

It has been predicted that the excision of the distal half of the small bowel would lead to weight-loss, decreased intestinal transit time, and eventually death. It was anticipated that the interposition of

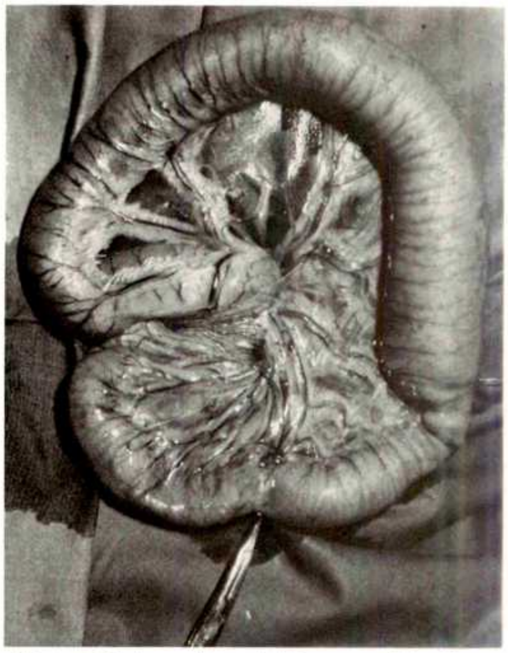

FIG. 1.—A single-vessel isoperistaltic segment of distal ileum in continuity with the remaining small bowel. Its position is shown by the forceps. Dilatation of the bowel proximal to the high-tone short segment is clearly shown.

Table I.—DETAILS OF THE RESULTS OF INTERPOSITION OF SHORT SEGMENTS OF SMALL BOWEL IN DOGS

	DOG

Pre-segment dilatation	No	Yes	No	No	Yes	Yes	No	No
Post-mortem appearance of small bowel	Normal	Proximal dilatation	Normal	Normal	Proximal dilatation	Proximal dilatation	Normal	Normal

single-vessel segments would, contrary to the results of interposing double-vessel segments, cause a degree of obstruction, increasing the intestinal transit time and thus promoting further absorption of intestinal contents. The expected outcome was observed in the small numbers studied.

It is of interest that the interposition of a short antiperistaltic double-vessel segment did not alter the behaviour of the small bowel and resulted in a similar weight-loss and decreased intestinal transit time as in the isoperistaltic double-vessel segment animals.

DISCUSSION

The question of adrenergic innervation of the smooth muscle of the small intestine is still not fully answered. Youmans (1972), in his presentation of the arguments for and against a significant role for the sympathetic system, concluded that it does have a marked influence on small-bowel motility.

Celender (1959) suggested that in the cat there are no extrinsic inhibitory nerves to the jejunum, and other workers (Kock, 1959; Kerwenter, 1965) have agreed with him. Celender's (1959) argument was that the sympathetic inhibition of smooth muscle was due to 'spill-over' of transmitter from the adrenergic vasoconstrictor nerves. There is no doubt about the action of both parasympathetic and sympathetic nerves on the vessels of the bowel (Padula, Noble, and Camishon, 1967, 1968) and their presence has been proved anatomically (Silva, Ross, and Osborne, 1971). While Silva and others (1971) disagreed with Celender (1959) and indicated that there are clearly demonstrable inhibitory nerves of sympathetic origin, they also noted that the chief projection of the extrinsic adrenergic fibres is upon blood-vessels. They showed, using the histochemical fluorescence technique (Falck and Owman, 1965), that the adrenergic sympathetic fibres occurred in greater concentration in association with arteries and arterioles than with veins. The discussion is further complicated by the known existence of inhibitory fibres within the vagus which are preganglionic, distinct from the sympathetic fibres, and non-adrenergic (Paton and Vane, 1963; Martensen, 1965; Campbell, 1966). The question of species difference may be of importance since the majority of the work quoted has been on cats. However, the primary, secondary, and tertiary plexuses in the myenteric plexus of the cat are similar to those demonstrated in the rabbit (Richardson, 1958) and in our earlier work we noted similar behaviour of gut segments in the rabbit and dog.

Whether the observations recorded are due to true anatomical variation or to a physiologically altered balance in inhibitory and stimulatory fibres is not clear. That the predicted behaviour was the observed behaviour of the segments examined suggests that the hypothesis of variable extrinsic autonomic innervation and the part that it plays in the behaviour of such segments may be correct, in the dog at least. If this is so then rules governing the use of such segments begin to emerge.

It is suggested that very short segments of the distal ileum supplied by one vascular pedicle should be observed following their isolation. If they visibly contract and remain contracted they will behave as if they are supplied by parasympathetic fibres only with no modifying sympathetic component and should, therefore, be avoided since they may cause a degree of obstruction, whether placed in an iso- or antiperistaltic manner, out of all proportion to their short length. Single-vessel distal ileal segments which do not contract and are, therefore, exhibiting low tone may be supplied by both parts of the extrinsic autonomic system and may then exhibit a low degree of obstruction when interposed in an antiperistaltic manner in keeping with their short length. We did not find, however, any such segments in the small group examined here.

Whenever two or more vessels supply a segment its behaviour will be predictable and will depend primarily on the length of the segment, since both components of the autonomic system will be represented.

If 7·5–10 cm. is the correct segment length in the human it should not be a high-tone single-vessel segment if a large degree of obstruction is to be avoided.

STRANGULATED EXTERNAL HERNIA ASSOCIATED WITH GENERALIZED PERITONITIS

By O. EKWUEME

DEPARTMENT OF SURGERY, MAKERERE UNIVERSITY, KAMPALA, UGANDA

SUMMARY

Thirteen patients are described in whom strangulated external hernia was associated with generalized peritonitis. The causes of this combination are discussed.

Although the features of peritonitis are usually quite distinguishable from those of an uncomplicated strangulated hernia, in virtually all the cases previously reported in the literature the presence of peritonitis was not recognized until operation for the hernia was undertaken. Increased awareness of this complication and a conscious effort to exclude it resulted in the correct preoperative diagnosis in 4 of our patients.

When the peritonitis is recognized preoperatively it is suggested that a laparotomy should be performed to deal with the intraperitoneal lesion, and that the associated groin hernia should be repaired by a preperitoneal approach through the laparotomy incision.

CRONIN and Ellis (1959) drew attention to the occasional occurrence of a collection of pus in an empty hernial sac in the course of a generalized peritonitis. They reported 5 cases of their own and reviewed another 27 instances collected from the world literature, all of which were diagnosed preoperatively as strangulated hernia. Maurath and Frauke (1966), in their review, stated that failure to recognize the associated acute abdominal disease in such cases results in a mortality of 60–70 per cent. At Mulago Hospital, Kampala (the National Hospital of Uganda), strangulated external hernia is by far the commonest emergency surgical condition (McAdam, 1961), and in a review of the cases seen in the past 2 years three different causes of the combination of strangulated hernia and peritonitis were encountered in 9 patients. Recently a special effort has been made to recognize the presence of peritonitis in patients presenting with strangulated hernia, and this has resulted in a correct preoperative diagnosis being made in 4 patients. This paper presents these two groups of patients and discusses the problem of preoperative diagnosis and treatment.

CASE REPORTS

Case 1.—N. A., a 40-year-old female, had had an umbilical swelling for 3 months. Four days before admission she developed severe colicky pain at the umbilicus which later became generalized and was associated with progressive abdominal distension. On examination her temperature was 38·2° C., pulse-rate 100 per minute, and blood-pressure 100/70 mm. Hg. There was generalized abdominal distension and tenderness, and a tender irreducible umbilical hernia, 5 cm. in diameter, was present.

At operation the umbilical hernia contained strangulated omentum, but thin greenish pus poured out of the peritoneal cavity. The incision was then extended and exploration of the abdomen revealed a generalized peritonitis resulting from a ruptured right tubo-ovarian abscess. The pus was drained and the abdomen was closed with drainage to the pouch of Douglas. The patient made a steady recovery, although she developed severe wound infection. Secondary suture was performed on the twenty-first postoperative day.

Case 2.—G. M., a 48-year-old male, had had a right inguinal herniorrhaphy 3 years previously. A lump had appeared in the left groin 9 months later but had been reducible and painless until 3 days before admission, since when the patient had had severe generalized abdominal pain and vomiting. On examination he was toxic and dehydrated. His temperature was 39·0° C., pulse 100 per minute, and blood-pressure 100/60 mm. Hg. There was generalized abdominal tenderness with diminished bowel-sounds, and a very tender irreducible left inguinal hernia was present. A diagnosis of strangulated inguinal hernia was made.

At operation the hernial sac was slightly thickened and haemorrhagic and contained only blood-stained fluid. A loop of bowel was retrieved from the peritoneal cavity and was found to be congested but viable. It was noted that the peritoneal cavity contained a large quantity of haemorrhagic fluid but this was attributed to the spontaneously reduced incarcerated loop of bowel. The patient failed to improve postoperatively and 2 days later the abdomen was more distended and remained tender and silent. The patient was thought to have peritonitis due to gangrenous bowel but at laparotomy acute haemorrhagic pancreatitis was found. After a stormy course a pancreatic pseudocyst became apparent on the fourteenth postoperative day. This was drained by cystogastrostomy on the twenty-fifth day, following which the patient made a satisfactory recovery. All his wounds healed by primary intention and he was discharged home after 35 days in hospital.

Case 3.—P. L., a 45-year-old male, gave a 2-day history of colicky abdominal pain and pain in the right inguinal region with vomiting and progressive abdominal distension. He had had a lump in the right groin for 12 years but this had not previously been tender. On examination he was in a satisfactory general condition. The abdomen was distended, there was marked guarding and rebound tenderness, and bowel-sounds were absent. There was a very tender irreducible right inguinal hernia.

On exploring the hernia the sac was found to be oedematous with areas of haemorrhage. It contained a loop of small bowel which was congested but viable. As a large quantity of blood-stained fluid poured out of the peritoneal cavity the abdomen was explored through a right paramedian incision, revealing the presence of acute haemorrhagic pancreatitis. The peritoneal exudate was sucked out, the peritoneum lavaged with normal saline, and the abdomen closed with non-absorbable sutures. Herniorrhaphy was performed. The ascites reaccumulated postoperatively but slowly cleared on treatment. The patient was discharged on the eighteenth postoperative day with no further complications.

Case 4.—C. K., a 47-year-old male, was admitted with a 3-day history of vomiting and a painful, irreducible inguinal lump; this lump had been present for 4 years but hitherto had been reducible. On examination the patient was febrile and dehydrated. The pulse-rate was 80 per minute and blood-pressure 120/90 mm. Hg. There was generalized abdominal tenderness and guarding and a tender, tense, and irreducible left inguinal hernia was present.

When the patient arrived in the operating theatre another hernia was discovered in his right groin and this was also tense, tender, and irreducible. A synchronous exploration was undertaken by two surgeons using two separate incisions, and on opening both hernial sacs copious pus poured out from the peritoneal cavity. The incisions were then converted into a low laparotomy incision and the peritoneal cavity was explored. No cause for the peritonitis was identified and the abdomen was closed with drainage. After initial improvement the patient's condition progressively deteriorated. Post-mortem examination was refused.

Case 5.—D. N., a 40-year-old male, had had a reducible right inguinal swelling for several years. At 10 p.m. on the day before admission he had had a sudden attack of colicky abdominal pain and the inguinal swelling became irreducible and rapidly enlarged. Vomiting started 2 hours after the onset of the abdominal pain and had been copious. On examination the patient was obviously in severe pain and was dehydrated; there was a large tender irreducible right scrotal hernia, and the abdomen showed visible peristalsis with rebound tenderness and guarding in the right iliac fossa.

Table I.—DETAILS OF PATIENTS WITH STRANGULATED EXTERNAL HERNIA ASSOCIATED WITH GENERALIZED PERITONITIS WHICH WAS NOT RECOGNIZED PREOPERATIVELY

CASE	AGE AND SEX	SITE OF HERNIA	SOURCE OF PERITONITIS	DURATION (d.)	TREATMENT	OUTCOME

CASE	AGE AND SEX	SITE OF HERNIA	SOURCE OF PERITONITIS	DURATION (d.)	TREATMENT	OUTCOME
10	65 M.	R.I.H.	Perforated typhoid ulcers terminal ileum	2	Laparotomy and suture. Hernia sac contained pus only	Strangulated R.I.H. on fourth postoperative day. Herniorrhaphy. Survival
11	32 M.	R.I.H.	Appendicitis	3	Appendicectomy. Preperitoneal herniorrhaphy	Uneventful. Survival
12	60 F.	L.F.H.	Gangrenous Richter's hernia	10	Laparotomy: resection and suture. Purse-string suture to neck of sac	Hernial sac abscess, drainage. Survival
13	55 M.	R.I.H.	Afferent loop strangulation (Philip, 1967), late stage	4	Laparotomy: resection and anastomosis. Purse-string suture to neck of sac	Gross scrotal abscess, drainage. Secondary suture. Survival

See footnote to *Table I* for key to abbreviations.

At operation the hernial sac contained two separate loops of small bowel which could not be reduced, and blood-stained fluid drained from the peritoneal cavity. The abdomen was then explored through a right paramedian incision, revealing volvulus of the small bowel with gangrene of 73 cm. of intestine. This was treated by resection and end-to-end anastomosis, the abdomen was closed, and herniorrhaphy was performed. Both wounds became infected postoperatively, requiring drainage. The patient was able to go home on the twenty-third postoperative day to continue wound dressings as an outpatient.

Case 6.—Y. K., a 30-year-old male, was admitted with a 2-week history of a painful lump in the left groin and anorexia. The pain had been somewhat worse since the morning of admission and the abdomen had been more distended. On examination his pulse-rate was 90 per minute, blood-pressure 130/90 mm. Hg, and he was slightly dehydrated. The abdomen was generally distended and tender but no rebound tenderness was elicited. There was a small, tender, irreducible, left inguinal hernia.

On exploration he was found to have a left direct inguinal hernia of the Richter's type through a defect in the conjoint tendon. The involved segment of the small bowel was gangrenous and adherent to the sac and a perforation had occurred at the level of the constriction ring. The abdomen was then opened through a right paramedian incision and a purulent peritonitis was discovered. The involved portion of ileum was resected and peritoneal toilet was performed. The abdomen was closed without drainage and herniorrhaphy was carried out. The patient made an uncomplicated recovery. A review of the abdominal radiographs revealed that apart from dilated loops of small bowel and multiple fluid levels, free gas was present under the right diaphragm and had been missed preoperatively.

Case 7.—N. E., a 31-year-old female, gave a 2-week history of colicky abdominal pain, vomiting, and constipation. On examination she was very dehydrated and shocked, with a pulse-rate of 140 per minute and a systolic blood-pressure of 55 mm. Hg. The abdomen was distended and tender and bowel-sounds were absent. There was a small peri-umbilical mass, which had not been previously noticed by the patient. Nasogastric aspiration yielded faeculent material. The patient was resuscitated with intravenous fluids, including 1 litre of blood, and at the time of operation her blood-pressure was 110/70 mm. Hg and pulse 120 per minute. She was found to have a small narrow-necked umbilical hernial sac which was distended with pus, and there was gross peritoneal soiling with intestinal contents. A formal laparotomy incision was made but the patient developed a cardiac arrest and could not be resuscitated. At post-mortem examination the generalized peritonitis was confirmed. There was fat necrosis around the umbilical site, and 45 cm. from the ileocaecal valve there was a circumscribed necrosis of the antimesenteric border of the ileum with central perforation. The final diagnosis was generalized peritonitis resulting from a strangulated umbilical hernia.

Case 8.—B. M., a 60-year-old male, complained of the sudden onset of generalized colicky abdominal pain and vomiting starting 3 days before admission, the pain later settling in the lower abdomen. He had not noticed a swelling in the right groin until the onset of the abdominal pain. On examination the patient was obviously very ill and was dehydrated and toxic. The pulse was 120 per minute and the blood-pressure was 140/90 mm. Hg. The abdomen was distended, tense, and generally tender with marked guarding, and the bowel-sounds were diminished. A tense irreducible right direct inguinal hernia was present.

At operation the defect was found to be in the conjoint tendon and the sac was distended with pus which was welling up from the peritoneal cavity. The abdomen was then opened and gross purulent peritonitis was discovered. A patch of the caecum close to the base of the appendix was gangrenous and perforated; this was thought to have been caused by strangulation followed by spontaneous reduction of a Richter's hernia involving the caecum. The gangrenous portion of the caecum and the adjacent appendix were excised, the defect was repaired in two layers, and peritoneal toilet was carried out. The abdominal wound was closed with drainage, and herniorrhaphy was performed. Both wounds became infected and had to be laid open; secondary suture was performed on the twenty-eighth postoperative day with satisfactory results.

Case 9.—N. E., a 60-year-old female, was admitted with a 10-day history of colicky abdominal pain, vomiting, and painful swelling in the right groin. On examination she was dehydrated, her pulse was 100 per minute, and blood-pressure 100/60 mm. Hg. The abdomen was generally distended, rigid, and tender with visible and palpable peristalsis. There was a small right femoral hernia which was hot, tender, and irreducible.

At operation the hernia was found to contain a gangrenous knuckle of the antimesenteric border of the ileum which was excised and repaired in two layers. However, copious amounts of pus flowed out of the general peritoneal cavity, and the abdomen was therefore explored through a right paramedian incision. This revealed a generalized purulent peritonitis but no other intraperitoneal lesion was discovered. Peritoneal toilet was carried out, the abdomen was closed without drainage, and a Lotheisen-Cooper herniorrhaphy was performed. Infection of the groin wound required removal of skin sutures for drainage. The patient was able to leave hospital on the eighteenth postoperative day and the wound subsequently healed satisfactorily.

The findings in these 9 patients are summarized in *Table I*. In addition, in 4 patients the presence of peritonitis in association with a strangulated hernia was recognized preoperatively and the details of these patients are summarized in *Table II*.

DISCUSSION

These cases demonstrate three different ways in which strangulated hernia and peritonitis can coexist. Zuckerkandl (1891) reported the case of a 55-year-old man with a 6-day history of a painful irreducible hernia, which on exploration contained pus only, secondary to a generalized peritonitis arising from a perforated acutely inflamed appendix. Since this report several similar instances have been reported (Cronin and Ellis, 1959). Seven of our patients (*Cases* 1–5, 10, and 11) belong to this category. In the reported cases in which the cause of the peritonitis was identified this included perforated peptic ulceration, pyosalpinx, and pneumococcal peritonitis, but perforated acute appendicitis accounted for the majority of cases—no doubt a reflection of its relative importance in the aetiology of generalized peritonitis. On the other hand, the rarity of appendicitis in our list (1 in 7 cases) may be explained on a basis of its relatively lower incidence in our patient population. The association of acute pancreatitis and strangulated hernia has not been previously reported, and although acute pancreatitis is an even less common cause of acute abdomen than appendicitis in Uganda it accounted for 2 of our 7 cases. Our cases support the finding of Cronin and Ellis (1959) that the presence of a large amount of fluid in the peritoneal cavity and delay in the treatment of the peritonitis are the factors which favour the development of this complication.

In 5 of our patients (*Cases* 6–9 and 12) the generalized peritonitis was caused by extension of infection from the gangrenous loop of bowel in the strangulated hernia. All 5 hernias were of the Richter's type: 2 inguinal (both direct), 2 femoral, and 1 umbilical hernia. The increased proneness to strangulation in direct hernias in the African has been noted by Cole (1964), and a high proportion of these are of the Richter's type. Gangrene of the knuckle of the bowel is a well-recognized feature of strangulated Richter's hernia because of the less severe symptoms that it produces. Bacterial invasion of the dying contents of the sac occurs if the obstruction is unrelieved. This is initially limited to the sac for days and sometimes for weeks; it usually terminates as a superficial abscess and is an occasional cause of external intestinal fistula. Generalized peritonitis may supervene because of extension of infection from the sac to the general peritoneal cavity, as in *Case* 9. More commonly, however, the necrosis of the hernial contents results in a perforation at the line of demarcation or spontaneous reduction, with free leakage of intestinal contents into the peritoneal cavity. The operative findings and the radiological demonstration of gas under the diaphragm in one of our patients confirm this sequence of events.

The most important factor in the development of this complication is the duration of the obstruction, and the fact that Richter's hernias produce relatively less severe symptoms often results in the patient not seeking medical help until severe complications ensue. In the case involving the caecum the duration of symptoms was 3 days, while in the 4 cases involving the small bowel symptoms had been present for 10 days or longer.

A third way in which generalized peritonitis coexists with strangulated external hernia is when the gangrenous loop of bowel lies in the peritoneal cavity. A rare but well-recognized example of this is Maydl's hernia (hernia-in-W). Philip (1967) has described a less known presentation in which the intra-abdominal portion of the small intestine proximal to the site of hernial obstruction in right inguinal hernia becomes obstructed by the caecum. He described 4 illustrative cases and claimed that 14·4 per cent of strangulated hernias in Tanzania were of this variety. Only 1 of our own cases conformed to this description (*Case* 13) and in this case the presence of peritonitis was recognized preoperatively. However, as the mortality from all types of strangulated hernia in Mulago Hospital is 3·0 per cent (McAdam, 1961) it is unlikely that cases of this presentation have passed unrecognized.

A correct preoperative diagnosis is notoriously difficult to make. None of our first 9 cases nor those reviewed by Cronin and Ellis (1959) was diagnosed correctly preoperatively. As the latter authors stated, 'it might appear surprising that difficulty should have arisen in differentiating between a peritonitis and a strangulated hernia, but the presence of a painful lump, about which the patient complains bitterly, makes it difficult for the surgeon to entertain any other diagnosis'. In all our patients the clinical picture in retrospect clearly suggested the presence of a generalized peritonitis, and it would appear that the failure of the surgeon to entertain any other diagnosis is the main obstacle to correct diagnosis. This state of affairs is not helped by the fact that whereas strangulated external hernia is a very common emergency its association with peritonitis is relatively rare. Nevertheless, failure to recognize this association when it occurs is an unjustifiable lapse in clinical acumen. Recently, by ensuring that every diagnosis of strangulated hernia is qualified with 'no evidence of generalized peritonitis' or otherwise, 4 such cases have been recognized preoperatively (*Table II*). As strangulated hernia is mostly dealt with by junior hospital doctors the adoption of this policy has proved successful in drawing attention to the possibility of this complication. Any patient with strangulated external hernia whose symptoms have lasted for more than 48 hours requires careful history-taking and examination to elucidate the sequence of events and to exclude the presence of generalized peritonitis.

Clearly a laparotomy is the best procedure when the presence of peritonitis is recognized preoperatively. This permits primary treatment of the intraperitoneal lesion and adequate peritoneal toilet. However, no conclusive evidence for the most satisfactory method of treating the hernia has emerged from these cases. In the 2 cases in whom peritonitis was due to acute pancreatitis the herniorrhaphy wounds healed primarily. On the other hand, only in 1 of the cases not recognized preoperatively in which the peritonitis was purulent did the wounds heal without complication. It can therefore be inferred from these results that a formal repair of the groin hernia through a separate incision is only justified when the associated peritonitis is not of the purulent type.

Three different methods were employed in the management of the hernia in the 4 patients who had primary laparotomy. In 1 patient the inguinal defect was left untreated and a formal repair was envisaged at a later date. However, the hernia reappeared on the fourth postoperative day with features of obstruction, and an emergency herniorrhaphy had to be performed. Strangulation of a pre-existing external hernia in the postoperative period has been described by Maurath and Frauke (1966) and Pfeffermann and Freund (1972).

In 2 patients the peritoneal connexion to the hernial sac was obliterated with a purse-string suture at the neck of the sac. In both patients the sac subsequently developed collections of pus requiring drainage, and in 1 patient with a scrotal hernia this was the source of prolonged morbidity. It is interesting that in 2 of the cases reported by Cronin and Ellis (1959) there were late collections of pus in the hernial sac following a generalized peritonitis. Although it is uncertain what is the ultimate recurrence rate following this method of treatment it has the advantage that it should prevent the possible occurrence of strangulation in the early postoperative period with the attendant risks of reoperation. However, it would appear that if this procedure is to be undertaken in the presence of purulent peritonitis the hernial sac should be drained through a separate stab incision.

In 1 patient the hernia was repaired through a pre-peritoneal approach to the internal ring (Nyhus, 1964) without complications. A separate incision was unnecessary as access to the pre-peritoneal space was achieved through the low abdominal incision. This procedure is technically easy, it offers a permanent cure for the inguinal hernia and is a minor addition to the operation. It is likely that the outcome from this approach will be superior to other methods and its further evaluation is indicated.

PANCREATIC REFLUX DURING OPERATIVE CHOLEDOCHOGRAPHY

BY A. CUSCHIERI AND J. HOWELL HUGHES

DEPARTMENT OF SURGERY, UNIVERSITY OF LIVERPOOL, AND LIVERPOOL ROYAL INFIRMARY

SUMMARY

Reflux of dye into the pancreatic duct was studied during operative choledochography performed in 211 conservative cases undergoing elective cholecystectomy. Reflux occurred with the same frequency whether the dye was injected by hand or by a constant-flow electrically driven pump. The outlined pancreatic duct was abnormal in 27 per cent of cases where a pancreatogram was obtained. No association was found between ductal stones and reflux of dye into the common bile-duct. Pancreatic reflux was associated with a low biliary pressure and segmental duodenal activity.

THE significance, if any, of reflux of contrast medium into the pancreatic duct during operative choledochography remains undecided. Its reported incidence varies from 8 to 32 per cent (Schulenberg, 1966; Whitaker, Parkinson, and Howell Hughes, 1968; Cuschieri, Howell Hughes, and Cohen, 1972). There is little doubt that this is a phenomenon which is usually obtained under highly uncontrolled conditions. Most published work on this subject has been done without due regard to such variables as the rate of injection of dye, pressure of injection, type of anaesthesia, and the use of premedicating drugs. This paper deals with the incidence and significance of pancreatic reflux in 211 consecutive cases undergoing elective cholecystectomy where an operative choledochogram was performed using either hand or pump injection of dye.

MATERIALS AND METHODS

Patients undergoing cholecystectomy were studied. The age range was 28–72 years. In the last 45 patients no drugs were administered for 10 hours before operation in all but 2 cases. Anaesthesia was carried out with thiopentone, nitrous oxide, and oxygen, a combination which has no effect on biliary pressures (Mallet-Guy, 1952). Muscle relaxation was achieved with D-tubocurarine. Each patient had an operative choledochogram through a Portex cannula inserted into the common bile-duct via the cystic duct. Dye (sodium diatrizoate, 40 per cent) was injected by hand (3–9 ml.) in the first 166 cases and by an electrically driven pump in the last 45 patients. The delivery of the pump was adjusted to a constant rate of 6 ml. per minute. The pressure exerted by the pump varied with the resistance to flow in the tubing but it averaged 25 mm. Hg. This method of manometric choledochography has been previously reported (Cuschieri and others, 1972) and the apparatus is shown in *Fig.* 1. It allows common bile-duct pressure monitoring during the injection of dye together with simultaneous intraduodenal pressure monitoring.

RESULTS

1. Incidence of Pancreatic Reflux.—Reflux of contrast medium into the pancreatic duct occurred in 23 out of 166 cases of hand injection (13·9 per cent) and in 8 out of 45 consecutive cases of pump injection (17·7 per cent). The overall incidence of pancreatic reflux was 15·4 per cent.

2. Incidence of Acute Pancreatitis.—Out of the total 211 cases, 1 patient developed acute pancreatitis after surgery with a rise in the serum amylase of 2050 Somogyi units per 100 ml. This patient did not have pancreatic reflux of sodium diatrizoate during operative choledochography.

3. The Outlined Pancreatic Duct.—Eight out of the 31 pancreatograms obtained showed an abnormal pancreatic duct. In all these the duct was dilated (diameter $>0·3$ cm.) and in 1 case calculi were present in the dilated pancreatic duct (*Fig.* 2). Three of these patients had chronic pancreatitis which was confirmed at operation.

4. Associated Choledochal Pathology.—In this series there were 18 cases of ductal stones and pancreatic reflux was present in only 1 of these. Moreover, in another case pancreatic reflux only occurred after removal of a stone from the lower end of the bile-duct (*Fig.* 3). The common bile-duct showed no radiological abnormality in 23 reflux cases with a normal pancreatic duct. Dilatation of the common bile-duct ($>1·0$ cm.) was present in 3 cases of pancreatic reflux where the outlined pancreatic duct was abnormal.

5. Dynamics of Reflux.—Reflux of sodium diatrizoate into the pancreatic duct was observed in 8 cases where dynamic pressure changes could be monitored simultaneously in the common-bile-duct and second part of the duodenum. In these cases pancreatic reflux was associated with a low resting choledochal pressure (mean 2·3 mm. Hg, range 0–6·0 mm. Hg). The average choledochal resting pressure for the 45 consecutive pump injection cases was 6·3 ± 4·0 mm. Hg. Reflux into the pancreatic duct occurred during injection but after the entry of dye into the duodenum in 6 cases and in these the choledochal sphincter was hypotonic as shown by the filling/pressure curve (*Fig*. 4). In the other 2 cases pancreatic reflux occurred after the injection of dye at a time when the duodenum showed gross segmental activity (*Fig*. 5).

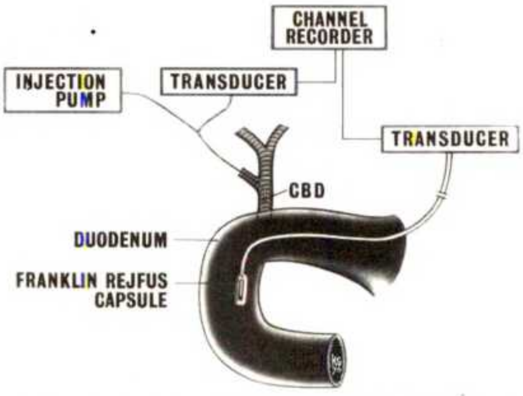

FIG. 1.—Apparatus used for manometric choledochography which allows dynamic pressure monitoring during operative choledochography using sodium diatrizoate (40 per cent) and a constant-flow injection pump.

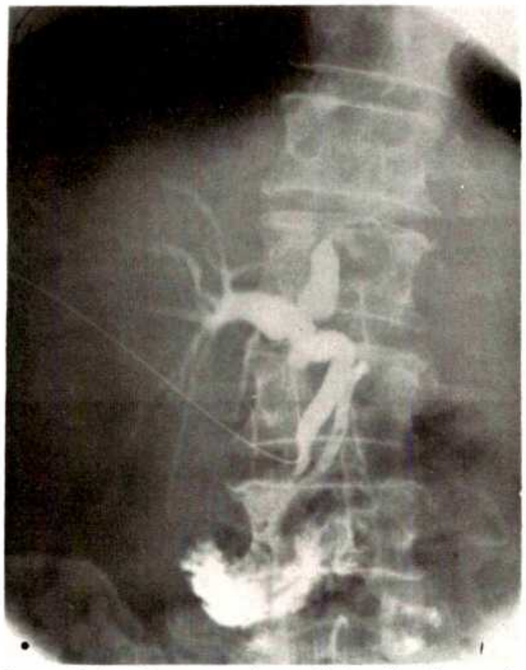

FIG. 2.—Reflux of contrast medium outlining a dilated pancreatic duct containing at least one calculus.

6. Follow-up of Patients.—All the cases of pancreatic reflux have been carefully followed up for periods extending from 14 to 46 months. Three were known to have chronic pancreatitis at operation and have required several hospital admissions for attacks of pancreatitis. One patient has developed a relapsing pancreatitis since her cholecystectomy 2 years previously. A barium-meal examination done at this stage showed reflux of barium into both the common bile-duct and the pancreatic duct (*Fig*. 6). None of the 23 cases with a normal outlined pancreatic duct has developed evidence of pancreatitis after operation.

DISCUSSION

Pancreatic reflux during operative choledochography occurred with the same frequency when dye was injected into the common bile-duct by a constant-flow pump at physiological pressure ranges as when injected by hand where excessive pressure peaks are known to be created.

Schulenburg (1966) considered pancreatic reflux as having no clinical importance and regarded it as an incidental finding at operative choledochography. The present authors, whilst agreeing that this is true in the majority of cases, consider it to be an overstatement as cases with an abnormal outlined pancreatic duct may have or subsequently develop chronic pancreatitis, as did 4 out of 8 cases with abnormal pancreatograms in the present series.

Following isolated reports of acute pancreatitis resulting from the use of lipiodol and water-soluble dyes (Zech, 1949), Howell and Bergh (1950) found a positive correlation between biliopancreatic reflux of contrast medium and elevation of the serum amylase. However, their work was done on postoperative T-tube choledochograms where the problem of sepsis complicates the picture, and the contrast media used were Thorotrast and Diodrast. The only case in the present series of 211 operative choledochograms that developed acute postoperative pancreatitis did not have pancreatic reflux during

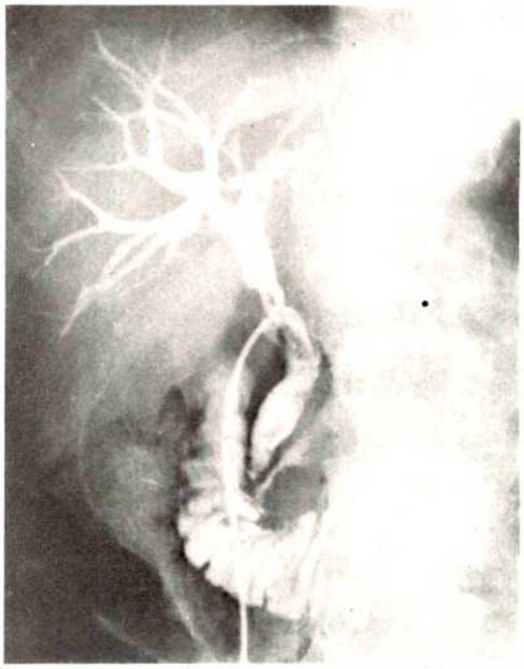

FIG. 3.—Pancreatic reflux of contrast medium seen after removal of a stone from the lower end of the common bile-duct.

operative choledochography. The present authors are in agreement with Schulenberg (1966) in considering postoperative pancreatitis after operative choledochography as extremely uncommon unless a large amount of dye is injected under pressure.

Experimental work in dogs suggests that reflux of dye into the pancreatic duct indicates biliary hypertension. Thus, Parry, Hallenbeck, and Grindlay (1955) have shown that in the dog the pressures in the common bile-duct are lower than those in the pancreatic duct during a fasting period, and this relationship existed in the majority of cases after meals. However, the anatomy of the periampullary region in the dog differs considerably from that of the

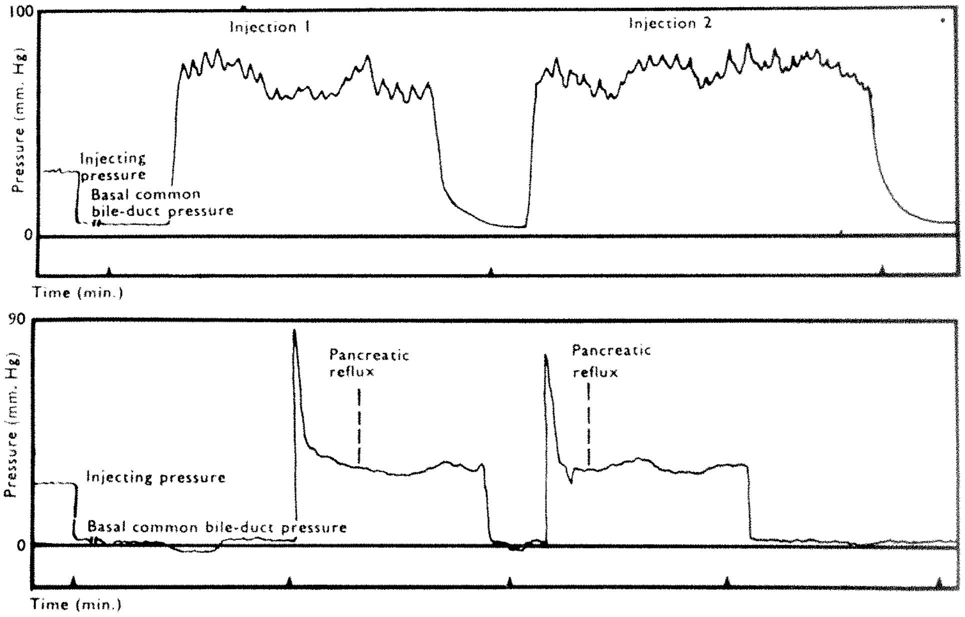

FIG. 4.—Pressure/filling curve in a case showing pancreatic reflux during injection of dye (*below*), compared with a normal choledochal pressure/filling curve (*above*). In the reflux case the common bile-duct pressure during injection of dye was similar to the pressure of injection. This indicates that the choledochal sphincter was offering little or no resistance to the flow of dye into the duodenum.

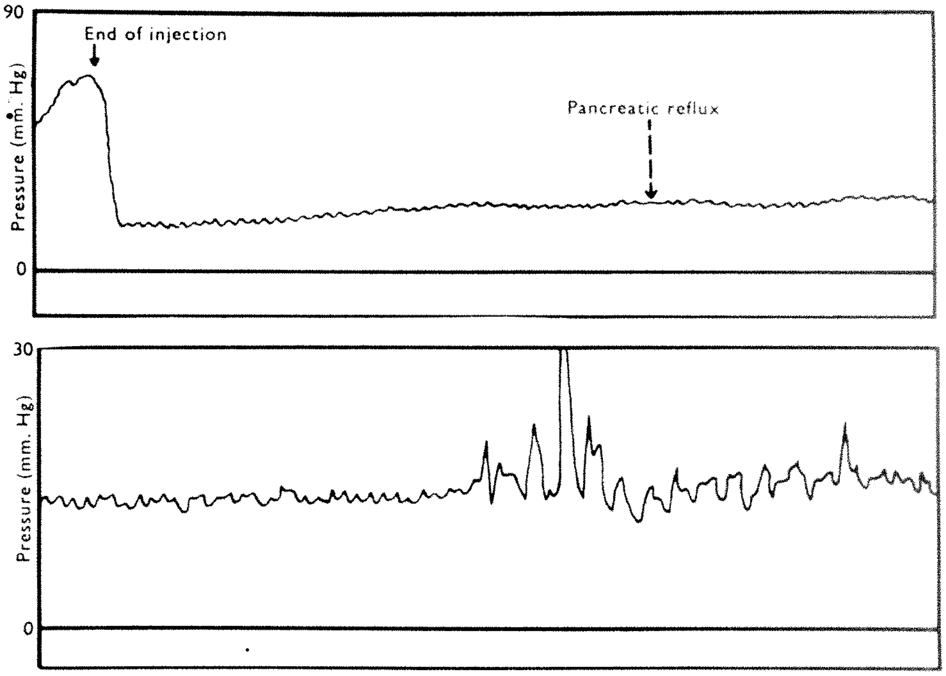

FIG. 5.—Pancreatic reflux occurring after injection at a time when the duodenum exhibited gross segmental activity. *Above*, common bile-duct pressure tracing. *Below*, duodenal pressure tracing.

human and findings from such animal experimentation are not therefore applicable to man. Our findings show that reflux of dye into the pancreatic duct is not associated with obstructive lesions of the choledochus and that the resting common bile-duct pressure in reflux cases is not elevated from the normal range. Reflux of contrast medium into the pancreatic duct can only occur when the choledochal sphincter is relaxed and this is in support of the work of Kune (1970).

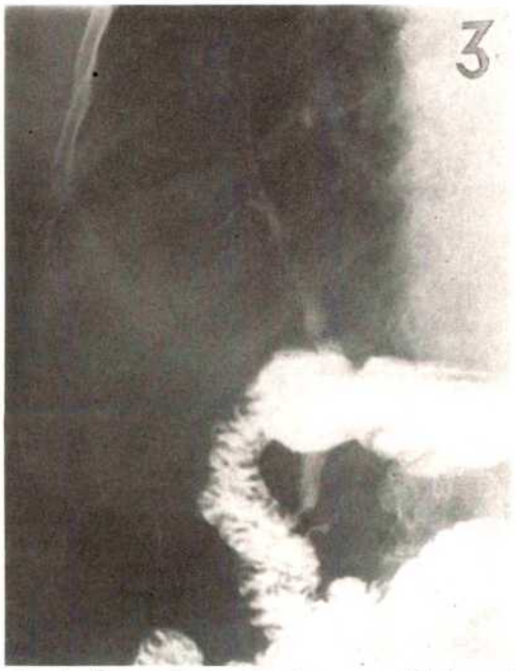

FIG. 6.—Reflux of barium into the common bile-duct and pancreatic duct during a barium-meal examination in a patient with chronic pancreatitis.

Analysis of the pressure/filling curves in reflux cases indicates the presence of a hypotonic choledochal sphincter in some cases where reflux of the dye occurred during injection, i.e., choledochopancreatic reflux.

Duodenopancreatic reflux was encountered in cases showing segmental duodenal activity and occurred after the injection of dye had stopped. One of the 2 patients exhibiting this type of reflux developed chronic pancreatitis and refluxed barium into both the pancreatic and common bile-ducts during a barium-meal examination carried out some months after cholecystectomy. This may be of some significance in view of reports (Muller-Weiland, 1963; McCutcheon, 1964; Anderson, 1967) of abnormal duodenal motility patterns in patients with chronic pancreatitis. It would seem that the normal choledochal sphincter guards against reflux of duodenal contents into the pancreaticobiliary tree and this reflux is potentiated by a hypotonic choledochal sphincter and/or the high pressure that can be generated by segmental activity in the duodenum. The suggestion of McCutcheon (1964) that such reflux may be the prime cause of pancreatitis requires further investigation. Other evidence in support of this hypothesis includes the report of Dreiling, Kirschner, and Nemser (1960) of a series of patients who developed pancreatitis in association with lesions producing distal duodenal obstruction. Experimentally, a closed-loop duodenal obstruction in dogs results in a severe necrotizing pancreatitis (Pfeffer, Stasior, and Hinton, 1957).

EARLY AND DELAYED OPERATION IN ACUTE GALL-STONE DISEASE

By G. S. SOKHI and C. J. LONGLAND
ROYAL INFIRMARY, GLASGOW

Summary

In a review of 157 patients admitted to hospital as emergencies with acute gall-stone disease it was found that 52 cases (33·1 per cent) had undergone definitive operation for gall-stones during the emergency admission in spite of an overall conservative policy in relation to operation. The results of these early operations are compared with those of operations delayed to a second admission in other patients of this series. There was no significant difference in mortality or morbidity, but there was a saving on average of 5 days in hospital for those patients who were operated on at the first admission.

The clinical manifestations of gall-stones can properly be referred to as 'gall-stone disease'; in this account we confine ourselves to manifestations arising in the biliary tract, thereby excluding the extra-biliary complications of pancreatitis and gall-stone ileus.

In the management of any acute episode of gall-stone disease conservative treatment is commonly preferred, no matter whether inflammatory or mechanical factors predominate. The policy of conservatism, aimed primarily at inflammatory disease, derives from the early part of this century and has been described as reserving surgical intervention within the first few days for uncertain diagnosis or uncontrolled infection (Till, 1963); acute symptoms usually subside, and operation necessary to deal with stones is planned as a delayed elective procedure at a later date. This view is based on the premiss that operation during the acute phase may be difficult or even dangerous; as a policy it succeeds in that the resulting mortality is generally low. Nevertheless, the timing of operation remains controversial and many have argued that early definitive operation without planned delay will avoid a waiting period, which is not entirely free from further painful attacks, and allow the patient to resume a normal life sooner; if operation is carried out in the first few days symptoms are at once abolished and further spread of inflammation beyond the gall-bladder is prevented (Devine, 1940; Glen and Thorbjarnson, 1963; Smith and Sherlock, 1964; Essenhigh, 1966; Payne, 1969; Van der Linden and Sunzel, 1970). It cannot be denied that these are strong arguments against delay.

The management of our own patients has been based on a conservative policy. Even so, considerable numbers of patients for various reasons have had early operation, defined here as operation during the emergency admission. We have compared the results in these patients with the results in those treated conservatively followed by delayed operation at a later admission in a group of patients all of whom were admitted initially as emergencies. If early operation is fraught with difficulties its results might be expected to compare poorly with delayed operation when a conservative policy is in operation, because patients selected for early operation will tend to be those in whom the disease is worse and has failed to respond to conservative management. It is not intended to suggest that all cases of acute gall-stone disease present the same management problem, for the spectrum is wide. Operation is of necessity early, even urgent, in some cases, but in the majority it can safely be postponed to a second admission. The question is whether postponement offers any advantage to this majority of patients.

THE SERIES

The patients presenting as emergencies with acute gall-stone disease admitted to two surgical units of the Royal Infirmary, Glasgow, during the years 1966–9 were surveyed. The units had similar admission arrangements and both adopted a conservative policy. All the patients were shown to have gall-stones either by operation or by radiology. The composition of the group of cases from each unit was very similar and they are therefore considered together, the total number of patients being 157 (45 men and 112 women).

The patients have been placed in three treatment groups in relation to the definitive operation, by which is meant cholecystectomy and, when required, operations to clear stones from the ducts, as distinct from simple emergency drainage operations of the gall-bladder or ducts.

Group 1: *Delayed Operation* (60 patients; 38·2 per cent).—Orthodox conservative management of the acute attack and discharge from hospital, followed by readmission at a later date and definitive surgery. The mean age of this group was 58 years (range, 21–81 years) and there was a male : female ratio of 17 : 43.

Group 2: *Early Operation* (52 patients; 33·1 per cent).—Definitive operation during the first (emergency) admission. The mean age was 56 years (range, 17–80 years) and the male : female ratio was 17 : 35.

Group 3: *No Operation* (45 patients; 28·7 per cent).—The patients in this mixed group either died without operation (3) or after cholecystostomy alone (1), declined operation (5), or failed to return after initial conservative treatment and discharge from hospital (11). A further 25 patients were considered unfit for definitive operation (15·9 per cent of the series). The mean age was 63 years (range 23–87 years) and the male : female ratio was 15 : 30.

The reasons for early operation are shown in *Table I*.

Of the 52 early operations, 8 were performed within 24 hours of admission and 7 more within the first 4 days, an incidence of 9·6 per cent of the whole series. The remaining 37 operations took place between 5 days and 4 weeks after emergency admission. This group is characterized by a high incidence of duct stones, which were found in 40 per cent of patients; ducts were explored in 56 per cent of the early operations. Acute cholecystitis, on the other hand, was present in 29 per cent compared with 45 per cent of the patients in group 1. Duct stones were found in 13 per cent of the patients in group 1, 28 per cent of the ducts being explored.

RESULTS

Three aspects have been examined in this survey: mortality in hospital, postoperative morbidity, and length of total hospital stay. In patients readmitted for delayed operation the total hospital stay is the sum of all the periods spent in hospital; there were usually two admissions, but in a few cases there were intermediate admissions for recurring acute episodes before the final admission for delayed operation.

Mortality.—*Table II* shows that after delayed operation (group 1) there was 1 death (1·8 per cent of the group). A man of 54 years died 3 days after cholecystectomy; no cause of death was apparent at the post-mortem examination. After early operation (group 2) there were 2 deaths (3·9 per cent of the group). One man of 65 years died from myocardial infarction on the second postoperative day and a woman of 72 years died with a stone obstructing the lower end of the common bile-duct 5 weeks after cholecystectomy without duct exploration. There is no statistically significant difference between the mortalities of groups 1 and 2 at the 5 per cent level.

The highest mortality was in the patients who had no definitive operation (group 3) where there were 4 deaths (8·9 per cent of the group). One death from renal failure in a man of 77 years followed cholecystostomy for empyema of the gall-bladder. Two men of 72 and 73 years respectively died from cardiopulmonary failure, and a woman of 58 died from massive pulmonary embolism; she was found at post-mortem examination to have also a carcinoma of the pancreas. The last 3 patients had no operation and they all died within 4 weeks of emergency admission.

The total number of deaths in the series of 157 patients was 7, an incidence of 4·5 per cent. There were 3 operative deaths in the 112 definitive operations (2·7 per cent), and there were 3 deaths during conservative treatment in 104 patients (2·9 per cent).

Postoperative Morbidity.—In a retrospective survey of this kind there was no set pattern for recording postoperative complications. The complications noted have been extracted from the case records and summated in *Table II*. The proportion of patients having recorded complications was about the same following delayed and early operation; for group 1, 30·0 per cent, and for group 2, 27·7 per cent.

As would be expected, and considering all the operative cases together, wound infection and pulmonary infection occurred most often, in 13·1 and 10·7 per cent of patients respectively. Cardiac and renal problems were the next most frequent complications, occurring in 6·3 and 5·4 per cent of patients respectively. Other complications, including postoperative peritonitis, haemorrhage, wound disruption, and jaundice, were infrequent, the incidence of none of these complications exceeding 4·5 per cent. No special note of deep-vein thrombosis had been made; it was only recorded twice when it resulted in marked swelling of the leg.

Postoperative stay in hospital (*Table III*) was slightly less on average after delayed operation (14 days) than after early operation (17 days).

Table I.—REASON FOR EARLY OPERATION

	No. of Cases

Total	30	14–55	25	7–62	14	7–50

Table IV.—SUMMARY OF THE FINDINGS IN 54 CASES OF ACUTE CHOLECYSTITIS

	GROUP 1	GROUP 2
No. of patients	39	15
Mortality	1 (2·6 per cent)	1 (6·7 per cent)
Morbidity	12 (30·8 per cent)	5 (33·3 per cent)
Mean total hospital stay (d.)	29	26
Difficult operations	5	0

Total Hospital Stay.—The patients in group 1 accepted advice to return for definitive surgery, having been treated conservatively at the emergency admission. While awaiting elective readmission 6 patients (10 per cent) were readmitted with further acute episodes of gall-stone disease; all these patients were later discharged when the acute episode had subsided.

The mean total hospital stay for group 1 patients (*Table III*), including the emergency and elective admissions and any intermediate admissions, was 30 days (range, 14–55 days). For group 2 patients, in whom surgery was completed at the first admission, the mean total hospital stay was 25 days (range, 7–62 days).

DISCUSSION

The results may be summarized as follows. Among the patients surveyed with acute gall-stone disease there was no statistically significant difference in the operative mortality between the patients who were operated on during the emergency admission (group 2) and those having delayed operation at a second admission (group 1), despite the general application of a conservative attitude to operation. Likewise, the frequency of recorded postoperative complications was nearly the same in both groups. The postoperative hospital stay, however, was a little longer in the patients who were operated on early; despite this, and of more importance, the total hospital stay was reduced by 5 days by early operation. Furthermore, 1 in 10 of the patients awaiting delayed operation was readmitted during the waiting period because of further attacks of pain; there must also have been others in whom attacks recurred but who did not require hospital admission. It should be added that 11 patients in group 3, in whom no operation was done because they failed to return for delayed surgery, would presumably have benefited from operation carried out during the emergency admission.

These findings are in keeping with those of Van der Linden and Sunzel (1970) in Sweden, who found the total hospital stay to be shortened by 8 days as a result of early operation. There were no deaths in their series after early operation, which was carried out during the emergency admission on the next convenient day after the diagnosis had been clearly established and the patient had been assessed as fit for surgery. They then examined sickness insurance payments and concluded that return to work was delayed by a factor of 50 per cent after delayed operation compared with early operation. Glen and Thorbjarnson (1963) and Essenhigh (1966) also commented on a saving of time in hospital achieved by early operation, without increased mortality.

Apart from the importance of the fitness of the patient (in our series 15·9 per cent of patients were considered to be unfit for surgery), a major question is the difficulty of operation and liability to complications in early surgery when florid acute cholecystitis is present. *Table IV* sets out the findings in our cases of acute cholecystitis. There was 1 postoperative death in both group 1 and group 2, while the frequency of postoperative complications was the same in the two groups. A survey of the operation notes suggests that none of the early operations was considered unduly difficult by the operator, whereas 5 were considered difficult after a waiting period and delayed surgery. Smith and Sherlock (1964) pointed out that difficulty at delayed surgery after a severe attack of acute cholecystitis is accepted by the surgeon though in fact if the operation had been done earlier it might have been found easier. In Payne's (1969) series of 398 patients with acute cholecystitis operation was performed within a few hours of admission in one-third of the cases without mortality. Smiddy (1970) undertook emergency cholecystectomy on the day of admission in 100 consecutive patients with clear-cut acute cholecystitis who were considered to be fit for surgery, and there were 3 deaths; these occurred in patients with a mean age of 75 years. This mortality compares favourably with 4 deaths in a series of 100 cases who were treated conservatively. However, it is possible that some of the latter cases might have been unfit for emergency surgery. The postoperative stay was greatly prolonged after emergency operation and Smiddy saw no place for routine emergency surgery in these circumstances. None of our patients who were operated on within 4 days of admission died.

The experience of the operator is of importance in any consideration of early operation, a point which is brought out by Van der Linden and Sunzel (1970). In our series almost all the early operations were done by consultant surgeons, whereas surgeons in training carried out one-third of the delayed operations of group 1.

The analysis of the cases of acute gall-stone disease presented here indicates that, given experienced surgeons, early definitive surgery after proper assessment of the patient is safe and offers some advantage over surgery delayed on conservative principles. Advancing the time of surgery has not interfered with full exploration of the ducts, which were explored in over half the cases operated on during the emergency admission.

Acknowledgements.—We are grateful to our colleagues, in particular Mr. J. Hutchison, for allowing us to survey their patients, and to Dr. P. W. Macfarlane for the statistical calculations.

MEASUREMENT OF STOMA SIZE FOLLOWING CHOLEDOCHODUODENOSTOMY BY TRANSDUODENAL CHOLANGIOGRAPHY

By J. M. HAM and W. SORBY

DEPARTMENTS OF SURGERY AND RADIOLOGY, THE PRINCE HENRY HOSPITAL, LITTLE BAY, SYDNEY

SUMMARY

Previous reports concerning the operation of choledochoduodenostomy have stressed the importance of an 'adequate' stoma. However, there does not appear to have been an attempt to measure the stoma size by some objective method.

The results with a new technique for the assessment of the stoma and duct system postoperatively are reported. The method involves the use of a transnasal guided catheter system with selective catheterization of the common bile-duct via the stoma. Accurate delineation of the stoma and ducts is then possible.

The stoma was successfully catheterized in 13 out of 16 attempts, and satisfactory radiographs were obtained in 1 other patient by a modification of the technique. The measurements of the maximum diameter of the stoma were considerably less than those reported previously; despite this the clinical result in the short term was good in all except the 2 patients in whom the stoma could not be demonstrated.

THE operation involving side-to-side anastomosis between the common bile-duct (or common hepatic duct) and the proximal duodenum has been termed 'external choledochoduodenostomy' (Capper, 1961), 'biliary fenestration' (Magarey, 1966), and 'side-to-side choledochoduodenostomy' (Degenshein and Hurwitz, 1967). These terms refer to basically similar procedures although there are some differences in technique. The operation is increasingly accepted as a useful procedure in patients with a variety of biliary disorders, and may be considered in patients with multiple or recurrent stones in the common bile-duct and in patients with carcinoma or benign lesions obstructing the distal common bile-duct. It has even been advised as a routine procedure in patients with common bile-duct stones (Magarey, 1966).

All previous reports stress the importance of an adequate stoma in order to avoid the complication of ascending cholangitis. Johnson and Stevens (1969) have compared two groups of patients with a stoma greater or less than 2 cm. in diameter with particular reference to the incidence of cholangitis. They concluded that a stoma size greater than 2 cm. was essential to the success of the operation. Other authors (Capper, 1961; Magarey, 1966; Burgess and Kidd, 1967) have drawn similar conclusions. In these papers it appears that the size of the stoma was assessed by the surgeon at operation, and presumably this assessment was based on the length of the incision in the common bile-duct. Unfortunately such a method, even if accurately performed, does not necessarily provide a correspondingly accurate measurement of the stoma after the anastomosis is completed.

We report here our initial results with a new method for the postoperative radiological assessment of the stoma and biliary tract following choledochoduodenostomy. The report deals only with patients having the operation for choledocholithiasis. The stoma is catheterized via a transnasal tube, the principle of the technique being similar to that of selective arteriography. A preliminary report of the method has been published (Sorby and Ham, 1972).

MATERIAL AND METHODS

Patients.—The procedure was performed 16 times in 15 patients. Their ages ranged from 24 to 81 years, all except 1 being over 50 years. All had jaundice due to choledocholithiasis, and 8 patients presented with clinical evidence of cholangitis. Cultures of bile taken at operation were positive in each of these 8 patients.

Table I.—MAXIMUM DIAMETERS OF THE COMMON BILE-DUCT AND STOMA IN THE PRESENT SERIES

14	40	14	20
15	29	16	25
Mean	24·1	14·6	14·4

The single young patient (*Case* 6, *Table I*) presented with the clinical features of oriental cholangiohepatitis, and in this instance the biliary stones were largely intrahepatic. This patient had two operations; at the first numerous stones were removed, intrahepatic strictures of the right and left hepatic ducts were dilated, and a choledochoduodenostomy performed. Five months later jaundice and cholangitis recurred. The second operation involved further dilatation of the strictures, removal of intrahepatic stones, and reconstruction of the choledochoduodenostomy.

All the procedures were performed between 12 and 20 days postoperatively.

Operative Technique.—The incision in the common bile-duct (or common hepatic duct) is oblique or vertical and as long as possible. The duodenum is mobilized and a similar oblique incision is made in its first part or near the junction of the first and second parts. The anastomosis is performed with continuous chromic catgut; an external layer of interrupted black silk sutures is added if the wall of the duct is markedly thickened.

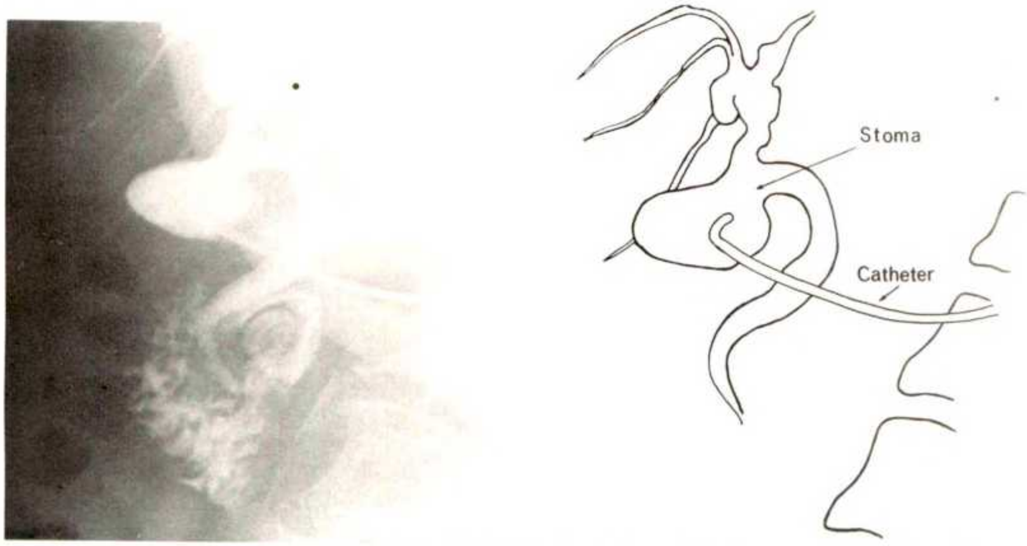

FIG. 1.—*Case* 3. Oblique view of the catheter in the duodenal cap, with dye outlining the stoma, bile-ducts, duodenum, and a duodenal diverticulum.

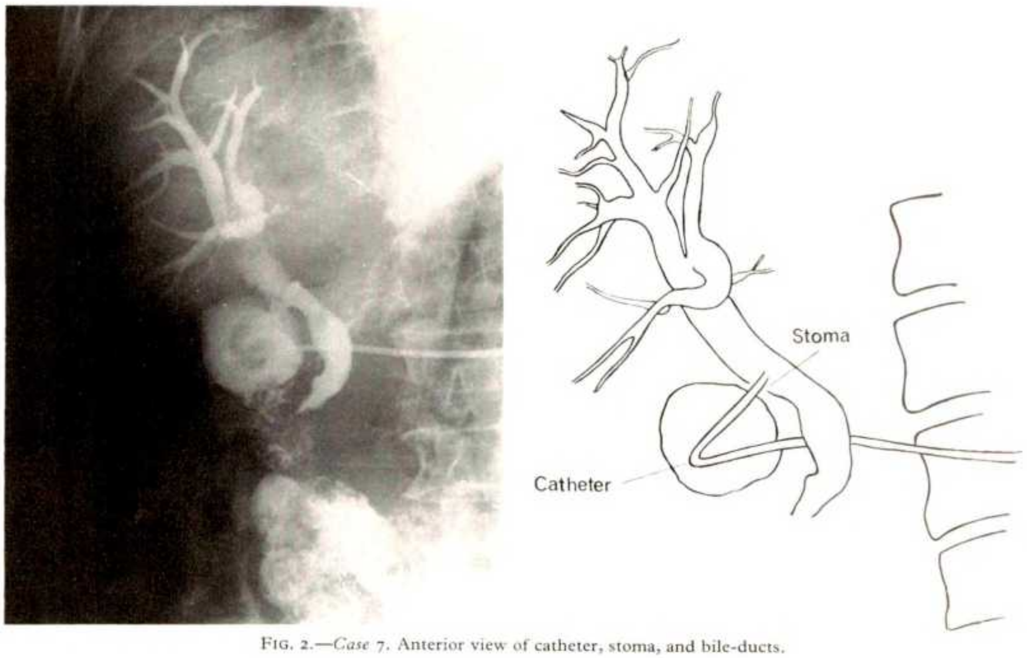

FIG. 2.—*Case* 7. Anterior view of catheter, stoma, and bile-ducts.

In most patients the surgeon estimated the stoma to be at least 20 mm. in diameter. The exceptions were the patient with oriental cholangiohepatitis, in whom the stoma was recognized to be small after each operation, and *Cases* 10 and 15, in whom the stoma was thought to be at least 25 mm. in diameter.

Radiological Technique.—The equipment consists of a Muller-USCI Guide System (United Catheter and Instrument Corporation), a remotely controlled guide-wire and catheter system originally designed for selective and superselective arterial catheterization for arteriography. A guide-wire tip may be flexed from 0° to 180° by a remote handle and a catheter with a soft flexible tip can be advanced out over it. The combined catheter/guide-wire assembly can be rotated 360° around its longitudinal axis.

The patient is premedicated with intravenous diazepam, 5–10 mg., on the radiological screening table and the nasal cavity is anaesthetized locally. The catheter/guide-wire assembly is passed transnasally through the stomach to the duodenum. The tip is flexed superiorly and rotated slightly posteriorly to 'seek' along the margin of the duodenum. When it engages in the stoma the soft tip of the catheter can be advanced over the stationary flexed guide-wire and up into the bile-duct.

Contrast (Urografin 60) is then injected to fill the biliary system and pass through the stoma into the duodenum. Films are taken in the following projections: supine, right oblique, left oblique, and lateral. Cine-films may be performed to show distension filling of the duct system with duodenal peristalsis.

An alternative technique if the stoma cannot be catheterized is to intubate the duodenal cap and inject denser contrast (Urografin 76). The procedure usually takes half to three-quarters of an hour and is well tolerated by the patients.

Measurement of Duct and Stomal Sizes.—The size of the common bile-duct before operation is measured on films obtained by intravenous or percutaneous transhepatic cholangiography. The maximum diameters of the common bile-duct and stoma after operation are measured on the transduodenal cholangiograms. The measurements are expressed to the nearest millimetre and no allowance is made for magnification factors.

RESULTS

Measurement of Duct and Stomal Sizes.—Catheterization of the stoma and transduodenal cholangiography were successful in 13 of the 16 attempts (*Table I*). One failure followed the first operation in the patient with oriental cholangiohepatitis. In this patient (*Case* 6) the diameter of the common bile-duct was at the upper limit of normal preoperatively and construction of an adequate stoma was more difficult than in the other patients. Catheterization of the stoma was unsuccessful in 2 other patients (*Cases* 1 and 13), but adequate films were obtained in *Case* 1 by the alternative method described above.

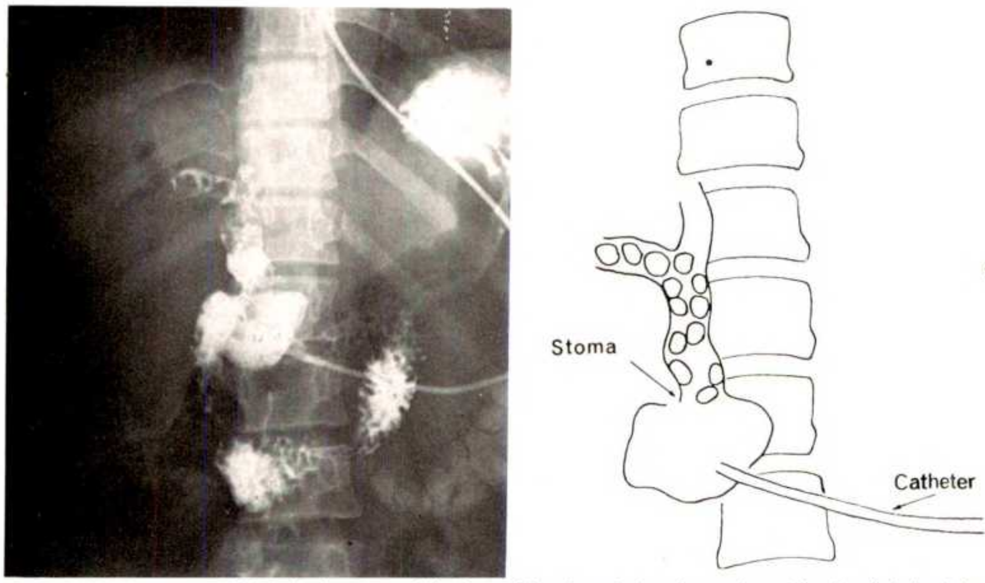

FIG. 3.—*Case* 6. Multiple stones and debris in the common bile-duct and intrahepatic ducts in a patient with oriental cholangiohepatitis.

The mean diameter of the common bile-duct before operation was 24·1 mm. (range, 13–40 mm.); after operation it was reduced to 14·6 mm. (range 8–20 mm.). The mean diameter of the stoma was 14·4 mm. (range 9–25 mm.). The largest diameter of the stoma was usually seen on an oblique or lateral film. Representative transduodenal cholangiograms are shown in *Figs*. 1, 2, and 3.

Clinical Results.—These operations have been performed over the past 2½ years and the period of follow-up is therefore short. Two patients have had clinical episodes of cholangitis. The first was the patient with oriental cholangiohepatitis (*Case* 6); presumably, the cholangitis was related in part to the small stoma and in part to recurrence of the intrahepatic strictures and stones. In the past 18 months he has had two further mild episodes of cholangitis which have subsided spontaneously within 6 days. *Case* 13, in whom transduodenal cholangiography was also unsuccessful, has had one episode of cholangitis which settled with antibiotics. It is anticipated that re-exploration will be necessary.

DISCUSSION

A choledochoduodenostomy stoma is usually regarded as 'adequate' if air is visible in the biliary tree on a plain film or if barium refluxes into the bile-duct from the duodenum during a barium-meal examination (Capper, 1961; Johnson and Stevens, 1969). Magarey (1966, 1971) has used aerated water with or without barium and recommends these methods for the assessment of the stoma and ducts. In our experience the presence of gas in the biliary tree does not necessarily permit measurement of stoma size or assessment of residual pathology in the bile-ducts, although it does of course indicate that the stoma is patent.

The barium-reflux test has three problems: first, reflux does not always occur even though the stoma is patent; secondly, the presence of large amounts of contrast in the stomach and duodenum may make it difficult to visualize the stoma and biliary tree; thirdly, the barium filling of the duct may be so dense as to obscure calculi or may be discontinuous and thus simulate them.

The present technique permits some precision in the demonstration of the stoma and ducts, in that small amounts of contrast can be injected serially. It was possible in this initial study to cannulate the stoma in 13 of 16 attempts. In 1 of the 3 failures an alternative technique—injection of dye into the duodenum adjacent to the stoma—was successful.

The method has permitted direct measurement of the stoma size in more than one projection, so that estimates of its maximum diameter were obtained. In all instances the stoma was considerably smaller than might have been predicted on the basis of the length of the incision in the common bile-duct. In most patients the stoma size was less than the figure of 20 mm. stated to be essential by previous writers. Despite this the clinical result in the short term has been good in all but 2 patients; in 1 of these (*Case* 6) the cholangitis was due to a combination of unusual factors, but both were presumed to have stomas which were too small.

It might be suggested that the reason for these marked differences in stoma size lies in the operative technique used in the present patients. This may be so; however, our technique appears to be similar in all essential respects to those reported previously, and is exactly the same as that reported by Hurwitz and Degenshein (1964). The use of the two-layer anastomosis in some patients could theoretically result in a reduction in stoma size; however, this addition to the technique was only used if the common bile-duct was markedly thickened. Thus, it is likely that the reason for the discrepancy between this and other reports is related to the differences in the methods of assessing the stoma. The reports of Capper (1961) and Madden, Chun, Kandalaft, and Parekh (1970) demonstrate that good clinical results may be obtained if the incisions in the common bile-duct and duodenum are sufficiently long (at least 25 mm.) and the anastomotic technique is satisfactory. However, the present results suggest that in these and other reports the size of the stoma in many patients may be considerably less than the 20 mm. quoted as essential. It is unlikely that the stoma will be much larger than the maximum diameter of the common bile-duct, and there may be little or no advantage to the patient in trying to achieve a stoma larger than this. It is important to note that the common bile-duct was reduced in size after operation in all our patients, but it is uncertain whether this reduction had any influence on the stoma. Finally, it is also uncertain whether a stoma which is adequate as a biliary by-pass for the patient with malignant obstruction is also adequate for the patient with a chronically dilated, thickened, and inflamed common bile-duct associated with calculi.

These questions will only be resolved by objective assessment of the stoma and biliary system soon after operation and subsequent long-term follow-up. The present technique provides the means for such objective assessment. In addition, it may also be useful in the investigation of the patient who presents with recurrent symptoms following choledochoduodenostomy; with the knowledge of the normal range of stoma size or of the postoperative stoma size of that particular patient an accurate diagnosis of stenosis of the stoma may be made.

SELECTIVE OR TRUNCAL VAGOTOMY?

FIVE-YEAR RESULTS OF A DOUBLE-BLIND, RANDOMIZED, CONTROLLED TRIAL

By T. KENNEDY, A. M. CONNELL,* A. H. G. LOVE, K. D. MACRAE AND E. F. ANNE SPENCER
ROYAL VICTORIA HOSPITAL AND THE QUEEN'S UNIVERSITY, BELFAST

SUMMARY

The 5-year results of a double-blind, randomized, controlled trial of selective versus truncal vagotomy, each with pyloroplasty, are reported. Of 100 patients entering the trial, 95 are available for study. There were 4 suspected or proven recurrent ulcers in the truncal group and 1 suspected but no proven recurrence in the selective group. The incidence of episodic diarrhoea was significantly less in the selective group; 4 mild and no severe cases compared with 11 mild and 2 severe cases among the truncal vagotomies. There was no severe dumping; mild symptoms were more common in the selective group but not significantly so. Miscellaneous dyspeptic symptoms were a little more common in the truncal group. Taking all these symptoms into consideration, the Visick clinical status of the selective group was superior. Weight changes, haemoglobin levels, and calcium levels were similar and satisfactory in each group. Selective vagotomy is superior to truncal vagotomy when each is combined with pyloroplasty.

THE operation most frequently used in Great Britain today for chronic duodenal ulcer is truncal vagotomy, combined with some form of pyloroplasty. During the 1960's the modification, introduced in 1948 by Franksson in Sweden and Jackson in the U.S.A. and called by them 'selective vagotomy', in which denervation is limited to the stomach, was strongly advocated by Griffith (1966) in the U.S.A., Burge (1964) in the U.K., Grassi (1970) in Italy, and Amdrup, Clemmesen, and Andreassen (1967) in Denmark. The main benefit claimed for the selective operation was a marked decrease in the incidence of episodic post-vagotomy diarrhoea. Both Marckmann, Baden, and Amdrup (1968) and Sawyers, Scott, Edwards, Shull, and Law (1968) claimed better gastric denervation and a lower incidence of positive insulin tests after the selective procedure.

A number of trials have been published in which the results of selective vagotomy have been compared with those of truncal vagotomy (Kraft, Fry, Wilhelm, and Ransom, 1967; Mason, Giles, Graham, Clark, and Goligher, 1968; Sawyers and others, 1968; Kronborg, Malmstrom, and Christiansen, 1970), but in none of these was the drainage procedure standardized and the follow-up conducted blindly. In an attempt to assess accurately the merits and demerits of these two vagotomies we have organized a prospective, double-blind, controlled trial.

PATIENTS AND PROCEDURE

During 1966 and 1967, 100 of our duodenal ulcer patients coming to elective operation were admitted to a prospective trial, 50 patients having truncal vagotomy and 50 having selective vagotomy, each with a Finney-type pyloroplasty (Kennedy and Connell, 1969). Patients were admitted to the trial only after the abdomen had been opened and the feasibility of vagotomy and of pyloroplasty had been confirmed. All patients with other significant gastro-intestinal disease, such as gastric ulcer, gall-stones, or pancreatitis, were automatically excluded. Patients having emergency operations and those inadequately assessed or unlikely to be available for follow-up were also excluded. At this stage a card was drawn by a nurse from a box containing 50 cards marked 'S' and 50 marked 'T' and the appropriate operation was performed. Selective vagotomy involved preservation of the hepatic branches of the anterior vagus and the coeliac branch of the posterior vagus. The pyloric branch of the hepatic nerve was not divided but both anterior and posterior nerves of Latarjet were divided. Eighty-one of the operations were performed by the same surgeon and the remainder by three other surgeons personally trained in the technique. The two groups were comparable in that there were 11 females in the selective group and 10 in the truncal group; the mean age of the groups was 47 and 45 years respectively. The severity of the ulcer diathesis, as judged by preoperative complications and by levels of gastric acidity, was comparable in the two groups. Annual follow-up was conducted by a physician who had no knowledge of which operation had been used in any individual patient. Careful inquiries and measurements were made in relation to pain, possibility of recurrence of the ulcer, nausea, vomiting of food or bile, dysphagia, heartburn, dumping, food intolerance, flatulence, weight change, alteration in bowel habit, diarrhoea, and patient satisfaction. Each patient was given a clinical grading using a simplification of the Visick grading as follows:—

1. No symptoms: a perfect result.
2. Mild symptoms: not troublesome.
3. More severe symptoms: some degree of disability.
4. Severe symptoms: recurrent ulcer, disabling side-effects, or reoperation.

Attention was particularly concentrated upon dumping and diarrhoea, which were graded + when quite trivial and often not complained of spontaneously, or + + when more severe and a significant nuisance to the patient. A patient was considered to be dumping when he complained of two or more of the following: fullness or discomfort in the epigastrium, nausea, sweating, weakness, palpitations, and the need to lie down after a meal, either large or small. Diarrhoea was defined as the passage of loose watery stools with urgency and sometimes incontinence, recurring at regular intervals of days or weeks. Sometimes there were only two or three motions in an attack; nevertheless the fear of incontinence, sometimes inhibiting the individual from going to work, could merit a ++ rating. The frequency of bowel habit, in motions per week, was recorded in each patient at the start of the trial and changes recorded at annual follow-up. All of these data depended upon the patient's statement. More objective data were provided by records of weight before operation and subsequently by haematological and biochemical studies at the end of 5 years.

---

* Present address: Mark Brown Professor of Medicine, University of Cincinnati, Cincinnati, Ohio, U.S.A.

RESULTS

Two positive findings emerged from our early follow-up studies which have already been published. First, there was a significantly lower incidence of positive insulin tests in the selective group, which led us to predict that there would ultimately be a lower incidence of recurrent ulcer. Secondly, at the end of 2 years there was a significantly lower incidence of episodic post-vagotomy diarrhoea (Kennedy and Connell, 1970). The object of the present paper is to publish the results of this trial 5 years after the last operation was performed.

Table II.—CLINICAL STATUS AT 5 YEARS

TYPE OF VAGOTOMY	MODIFIED VISICK GRADING					
	1	2	Successes	3	4	Total Failures
Selective	27	20	47	0	2	2
Truncal	29	11	40	2	4	6

P = 0·1506 (not significant).

All the 100 patients survived operation and all have been interviewed at least once since operation. Since operation 3 patients (1 in the selective, 2 in the truncal group) have died; 2 with bronchial carcinoma and 1 with congestive heart failure. An additional patient survives with a treated breast cancer. It has been difficult to trace patients and to arrange personal follow-up in the Belfast area during the past 3 years, so that it is scarcely surprising that 2 patients have been lost to follow-up (*Table I*), both from the truncal group; they were last seen at 2 years and 3 years after operation respectively. Forty-nine of the selective group and 46 of the truncal group have been followed up at 5 years, all of whom were personally interviewed at this time except 5 patients (3 in the selective group and 2 in the truncal group) for whom we have relied upon information supplied by questionnaires filled in by the patient or his family doctor. Each of these patients had been seen at earlier follow-up and the postal evidence simply confirmed the previous findings. Many patients have been seen after 6 and 7 years, but we have ignored these data as we wished to compare the status of all the patients at the same point in time—5 years after operation.

In the analysis of the results Fisher's exact probability test has been used throughout.

Clinical Grading.—Using the modified Visick grading described, we have found 2 failures (grades 3 and 4) in the selective group and 6 failures in the truncal group (*Table II*). Of the absolute failures (grade 4) in the truncal group, all were cases of suspected or proven recurrent ulcer, whereas 1 in the selective group came to reoperation because of a malfunctioning pyloroplasty with no ulcer recurrence. The two grade 3 patients in the truncal group each had severe episodic diarrhoea. Visick gradings for the 5 patients who had either died or been lost to follow-up are available for 2 or 3 years after operation. The patient in the selective group was graded 1; in the truncal group two patients were graded 1, one patient graded 2, and one patient graded 3.

Recurrent Ulceration.—The object of any vagotomy is to cure the original duodenal ulcer and to avoid recurrent ulcer. At 5 years there were 3 recurrent ulcers which had been proven at operation as well as a fourth suspected recurrence in the truncal group, compared with only 1 suspected recurrence in the selective group (*Table III*). This difference was predictable in the early stages of the trial because of the lower incidence of positive insulin tests after selective vagotomy already reported, only 2 of 45 tests after selective operation being positive compared with 9 of 45 tests after truncal vagotomy. The recurrence after selective vagotomy and 2 of the truncal cases presented during the first year after operation, with the 2 others presenting in the third and fourth years. The overall incidence of suspected and proven recurrence of 5·4 per cent (2 per cent after

P = 0·0156 (significant).

selective vagotomy) may well rise with the passage of time.

Diarrhoea.—We have not been concerned with diarrhoea in the early postoperative period but rather with persisting episodes of explosive watery diarrhoea, sometimes with incontinence, recurring at intervals of days, weeks, or months. Diarrhoea has occurred in 13 patients after truncal vagotomy and in 4 patients after selective vagotomy, a statistically significant difference. In only 2 patients, both in the truncal group, was the diarrhoea sufficiently severe to be a major disability (*Table IV*). Occasionally this curious episodic diarrhoea phenomenon does not manifest itself until some years after operation, while other patients with episodic diarrhoea at earlier follow-up may lose their symptoms when they discover provocative articles of diet and learn to avoid them. It is impossible to measure the precise severity of this symptom in each case, but 6 patients in the truncal group and only 1 in the selective group had attacks more often than once a month, and 4 patients in the truncal group and none in the selective group had more than four motions per day during an attack. Loose watery motions were produced at the rate of 1558 per annum by the truncal group compared with 300 per annum by the selective group.

Selective	49	37	+4·5
Truncal	46	32	+4·0

$P = 0·6458$ (not significant).

Bowel Habit.—In each case the preoperative bowel habit was expressed in motions per week, and the same information was sought at the 5-year follow-up, episodes of diarrhoea being excluded. In both groups the majority of patients stated that there was an 'improvement', with a mean increase of 2·3 motions per week in the selective group and 2·0 in the truncal group, not a significant difference. Constipation was not a problem at this stage; only 4 patients in the selective group and 7 in the truncal group claimed a decrease in bowel frequency. These results were similar to those found at the first annual review.

Dumping.—One of the principal reasons for adopting vagotomy instead of partial gastrectomy as the operation of choice for duodenal ulcer was the high incidence of dumping after gastrectomy. It was disappointing, therefore, at our first review to find dumping in nearly 40 per cent of this series; at that time no less than 17 patients were given a ++ rating, indicating symptoms sufficiently severe to be a nuisance. At 5 years the position had improved, probably because patients had learnt to adjust their diets appropriately and thus diminished both the frequency and the severity of this symptom complex.

Table VIII.—HAEMATOLOGY AT 5 YEARS

TYPE OF VAGOTOMY	NO. OF CASES	HAEMOGLOBIN (g. per cent)		MEAN CORPUSCULAR VOLUME (cu. μ)	
		Mean	No. under 13 g.	Mean	No. over 100
Selective	36	14·8	3	92·5	2
Truncal	37	14·6	3	91·7	2

Table IX.—CALCIUM AND ALKALINE PHOSPHATASE AT 5 YEARS

TYPE OF VAGOTOMY	NO. OF CASES	MEAN CALCIUM LEVEL (mg. per cent)	ALKALINE-PHOSPHATASE LEVEL (K.A. units)	
			Mean	No. over 15 K.A. units
Selective	34	9·4	8·7	2
Truncal	36	9·0	15·6	4

There were now no cases meriting ++ grading, but the continuing incidence of 27 per cent in the selective group is disturbing (*Table V*); the difference is not statistically significant. It must be stressed that this high incidence is directly related to the diligence of the interviewing physician. Many patients did not make any spontaneous complaint, and the dumping only came to light after close and careful questioning. The same is true of the other dyspeptic symptoms investigated.

Miscellaneous Dyspeptic Symptoms (*Table VI*).—By far the commonest of these was flatulence, and this was seen more often in the truncal group; it was hardly ever considered to be an important problem. Nausea, with or without vomiting, was not sufficiently common to cause comment. Bile vomiting occurred in only 2 patients of each group and was probably a product of the pyloroplasty rather than of the vagotomy. Gall-stones were not diagnosed in any patient from either group during the follow-up period.

In the early postoperative phase 9 patients (6 from the selective group) had significant dysphagia, 4 requiring oesophagoscopy and dilatation. Only 1 patient (from the truncal group) had dysphagia at

5 years. The low incidence of heartburn probably indicates a low incidence of hiatus hernia and oesophageal reflux at this stage, perhaps because an attempt was made to narrow the hiatus when it was found to be lax at the primary operation.

Nutritional Changes.—Objective data have been collected in relation to weight changes and haematological and biochemical measurements.

At the 5-year follow-up 37 of the selective group and 32 of the truncal group had gained weight, the mean gain being 4·5 kg. in the selective group and 4 kg. in the truncal group, which is not a significant difference and is very similar to the changes found at the end of the first year (*Table VII*).

Haematological surveys at the end of 5 years were carried out on 73 patients (*Table VIII*). The selective group had a mean haemoglobin level of 14·8 g. per cent, and in the truncal group the corresponding figure was 14·6 g. per cent. There was no patient with a haemoglobin level below 12·0 g. in either group and only 3 patients in each group had a level under 13·0 g. Owing to technical problems we were unable to obtain measurements of vitamin B_{12} in a sufficient number of patients, but the mean corpuscular volume has been studied as an index of incipient macrocytic anaemia. On the auto-analyser a figure up to 99 cu.μ is accepted as normal. Readings between 100 and 106 cu.μ were found in 2 patients in each group.

To investigate the possibility that skeletal problems might ultimately arise in either group the serum-calcium and alkaline-phosphatase levels were studied (*Table IX*). There was no case of hypocalcaemia in either group and there was no significant difference between the selective and truncal vagotomy groups in the mean levels of calcium, which were 9·4 and 9·0 mg. per cent respectively. Raised alkaline-phosphatase levels could have indicated increased skeletal activity, but we did not differentiate between bony and hepatic alkaline phosphatase in this study. Higher levels were found after truncal vagotomy and 4 of this group, compared with 2 of the selective patients, had levels above 15 K.A. units. None of these patients was jaundiced; none was adolescent and none was known to have Paget's or other sketalel disease.

Other biochemical levels, including glucose, uric acid, cholesterol, albumin, and transaminases, were routinely checked by the auto-analyser, but the results revealed nothing worthy of recording here.

DISCUSSION

There can be no dispute about the need for objective data in the assessment of selective vagotomy. The obvious yardstick must be a truncal vagotomy and it is essential in any trial that the drainage procedure is standardized, as pyloroplasty and gastro-enterostomy may give very different results. For example, Goligher, Pulvertaft, Irvin, Johnston, Walker, Hall, Willson-Pepper, and Matheson (1972) found an incidence of recurrent ulcer after truncal vagotomy and pyloroplasty about twice as great as that after truncal vagotomy and gastrojejunostomy. On p. 949 of this Journal the results of a trial of selective vagotomy and pyloroplasty versus selective vagotomy and gastrojejunostomy conducted on similar lines to this present trial are reported.

In planning this study we had to decide whether to limit the study to the practice of one surgeon and his team or to involve a whole hospital in order to collect more cases more quickly. We opted for the former as we felt that uniformity of technique was more important than larger numbers. It was important to ensure, as far as possible, that the extra-gastric fibres really were preserved in the selective vagotomy patients, though one can never be absolutely sure of this preservation. Failure to preserve fibres could be the cause of some anomalous published findings. Uniformity of follow-up assessment was also of obvious importance. All the early follow-ups were conducted by A. M. C.; at 5 years each patient has been seen by A. H. G. L. or E. F.A.S. and graded by agreement between them.

It is difficult to achieve 100 per cent follow-up and obviously impossible when 3 patients die from causes which are presumably unrelated, though one might speculate that both the duodenal ulcer and the bronchial carcinoma were related to smoking in 2 of them. A lost-to-follow-up rate of only 2 per cent in Northern Ireland today is surprising. If each of these 6 patients had retained their earlier grading the overall pattern of results would not have been altered. Since our reported first-year follow-up the failure rate (Visick grades 3 and 4) of 13 per cent has fallen to only 8·5 per cent owing to the better control of, or acceptance of, dumping, diarrhoea, and other side-effects. At the same time failures due to recurrence have increased. Fawcett, Johnston, and Duthie (1969) found that about three-quarters of all their recurrent ulcers appeared within the first year, and this was true of 3 of our suspected and proven recurrent ulcers. Two further suspected recurrences, 1 from each group, have subsequently presented after the 5-year follow-up assessment, and we may yet see more cases in later years. The 5-year recurrence rate of 2 per cent after selective vagotomy is quite acceptable, though 9 per cent after truncal vagotomy is too high by our standards. It may of course be that the recurrence rate is linked to the pyloroplasty, and gastrojejunostomy would have given a lower recurrence rate. This was the experience of Goligher and others (1972), whose suspected and proven ulcer recurrence rate 5–8 years after operation was 14 per cent after truncal vagotomy and pyloroplasty compared with 8·4 per cent after truncal vagotomy and gastrojejunostomy.

The apparent lower incidence of recurrence after selective vagotomy may well be linked to the better denervation indicated by insulin tests carried out 10 days after operation. The validity of these early tests has been questioned, but in our experience the 10-day status has been maintained in 80 per cent of patients (Kennedy, 1973). There is no clear-cut reason why denervation should be better after selective vagotomy, unless it is that this operation demands more care from the surgeon. If a lower incidence of recurrent ulcer, suspected from this trial, is confirmed it would constitute a major reason for preferring selective vagotomy for routine use.

Though the cause of episodic diarrhoea after vagotomy has never been fully elucidated, it has been shown by McKelvey (1970) to be related to rapid uncontrolled gastric emptying. The incidence of diarrhoea has been disputed, varying between 2 per cent (Elliott-Smith, Painter, and Porter, 1961) and 38 per cent (Harkins, Stavney, Griffith, Savage, Kato, and Nyhus, 1963), but definitions vary and the actual incidence of troublesome diarrhoea after truncal vagotomy is probably about 5 per cent (Barnes and Cox, 1969). Virtually all the published figures point to a lower incidence of episodic diarrhoea after selective vagotomy than after truncal vagotomy, whether the drainage procedure has been pyloroplasty, gastrojejunostomy, or antrectomy (Elliott-Smith and others, 1961; Harkins and others, 1963; Burge, 1964; Sawyers and others, 1968; Hendry and Abdulla, 1969; Grassi, 1970; Kronborg and others, 1970). We believe that our trial is the only published one which had been fully controlled, double blind, and with uniformity of the drainage procedure, and we have also found significantly more diarrhoea after 2 years and again after 5 years in the truncal group. The reason for this is not clear. The overall increase in bowel frequency seen equally in both groups was independent of diarrhoea and was not a disability; indeed many patients were delighted to find that their long-standing constipation had been relieved.

Dumping has become less severe with the passage of time and there were no cases of disabling dumping at the 5-year follow-up. One patient with severe dumping at the third year was subsequently lost to follow-up, and others appear to have mastered this problem by simple dietetic adjustment. Why dumping remains as a minor problem in 13 patients after selective vagotomy compared with only 5 after truncal vagotomy we cannot explain, though this difference does not reach statistical significance. An excess of mild dumping after selective vagotomy was also reported by Sawyers and others (1968). Of the miscellaneous symptoms, the commonest was flatulence, but this was seldom a problem. It might seem reasonable to postulate that the preservation of vagal afferents from the upper small bowel could be contributory. Nausea and vomiting were not sufficiently often seen in either group to constitute a problem. Looking at these symptoms together, it seems that selective vagotomy is favoured, but the adverse figures with regard to dumping offset these minor symptoms. The clinical grading table shows more qualified successes (grade 2) and fewer unqualified successes (grade 1) in the selective group.

Gain of weight after operation is a widely used parameter of success, but we have not found any correlation between weight change and Visick grading. Often improvement in Visick grading is associated with some loss in weight and vice versa. Many preoperative patients are overweight as they drink a great deal of milk to control ulcer symptoms. Relief of dyspepsia allows them to omit milk and thus lose weight after a successful operation. Pain from recurrent ulcer may lead to a return to milk and a further gain of weight.

Calcium and alkaline-phosphatase measurements appear to favour selective vagotomy marginally, but the striking finding is the absence of anaemia in each group. Unfortunately we do not know how many patients had been on iron therapy. These figures are in marked contrast to those of Wheldon, Venables, and Johnston (1970), who found a very high incidence of anaemia, hypocalcaemia, and weight-loss 15 years after truncal vagotomy and gastrojejunostomy. Although the blood-calcium levels were all normal the small number of raised alkaline-phosphatase levels give just a hint that metabolic bone disease may become a problem in later years.

The evidence of this trial with regard to diarrhoea, coupled with the low incidence of recurrent ulcer and the smaller incidence of all other symptoms, with the exception of dumping, leads us to advocate selective rather than truncal vagotomy in cases where a drainage procedure is required. Dumping and other symptoms may well be a product of pyloroplasty rather than of either type of vagotomy.

The operation of the future may well prove to be proximal gastric (highly selective) vagotomy and we are one of several teams currently assessing this procedure. To do this properly a control operation is required and selective vagotomy, with standardized drainage, is ideally suited to this purpose.

PYLOROPLASTY VERSUS GASTROJEJUNOSTOMY

RESULTS OF A DOUBLE-BLIND, RANDOMIZED, CONTROLLED TRIAL

By T. KENNEDY, G. W. JOHNSTON, A. H. G. LOVE, A. M. CONNELL,* and E. F. ANNE SPENCER
ROYAL VICTORIA HOSPITAL AND THE QUEEN'S UNIVERSITY, BELFAST

SUMMARY

A double-blind, randomized, controlled trial of Finney pyloroplasty and gastrojejunostomy, each with selective vagotomy, is reported. There were no operative deaths but 5 patients have subsequently died or have been lost to follow-up, leaving 94 patients, with a mean follow-up time of 3¼ years. There has been 1 proven recurrence after gastrojejunostomy and 2 after pyloroplasty, with 1 further suspected recurrence in each group. The clinical grading marginally favoured gastrojejunostomy. There was no significant difference in the incidence of bilious vomiting, dumping, diarrhoea, or other disturbances, but there was a significantly greater increase in bowel frequency after pyloroplasty. Weight changes were similar, and there was no gross anaemia or calcium deficiency in either group. Gastrojejunostomy is reversible and pyloroplasty is not, and therefore we recommend gastrojejunostomy as the drainage procedure of choice when drainage is necessary after vagotomy.

TRUNCAL vagotomy with pyloroplasty is the operation most commonly used in Britain today in the treatment of chronic duodenal ulcer (Alexander-Williams, 1973). The present study was designed to test the widely held belief that pyloroplasty is superior to gastrojejunostomy when a drainage procedure is required to supplement vagotomy. Pyloroplasty, by causing less distortion of the normal anatomy, has the greater aesthetic appeal. It is recommended by Burge (1964), Wise and Ballinger (1969), and Wastell (1972), who regard it as a more physiological operation. In reviewing the two types of drainage in association with truncal vagotomy, Goligher and Pulvertaft (1969) formed the impression that gastroenterostomy gave better overall results, but the cases reviewed were not entirely comparable. In a recently published controlled trial carried out in Glasgow pyloroplasty was compared with gastrojejunostomy in patients having a truncal vagotomy. The only significant difference found at a mean follow-up of 4 years was a higher incidence of bilious vomiting after gastrojejunostomy (Kennedy, MacKay, Bedi, and Kay, 1973).

PATIENTS AND PROCEDURE

During the years 1968 and 1969 patients under the care of one surgical team coming to elective operation for chronic duodenal ulcer were eligible for admission to this trial. Fifty were treated by selective vagotomy and pyloroplasty, and 50 by selective vagotomy and gastrojejunostomy. The pyloroplasty was of a modified Finney type (*Fig.* 1) similar to that described by Wastell (1972), with an opening between 6 and 10 cm. in length which was closed in such a way as to approximate the antrum to the duodenum. Gastrojejunostomy was retrocolic and juxtapyloric with the stoma as close as possible to the duodenojejunal flexure. The stoma was normally 5 cm. in length with a range of 4–8 cm. In every case a double-lumen gastrostomy tube (Burns and Menzies, 1966) was used, thus eliminating nasogastric intubation and intravenous feeding. One limb of this tube was sutured to the gastric mucosa 1–2 cm. proximal to the anastomotic line.

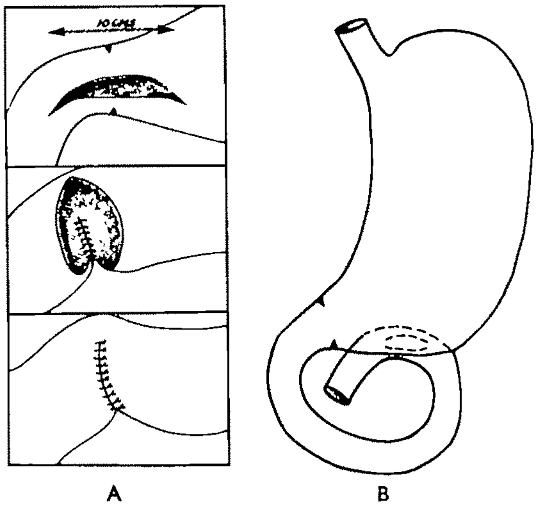

FIG. 1.—A, Pyloroplasty was a modified Finney type. B, Gastrojejunostomy was as close as possible to the pylorus and also to the duodenojejunal flexure.

No patient was accepted for this trial until the abdomen had been opened, the diagnosis confirmed, and the feasibility of selective vagotomy and of either type of drainage procedure established. Any patient with other significant gastro-intestinal disease, for example, gastric ulcer, gall-stones, or pancreatitis, was automatically excluded from the trial. Patients having emergency operations and those who were for any reason unlikely to be readily available for follow-up were excluded. Once a patient was accepted into the trial the drainage procedure to be used was decided by a nurse drawing a card from a box. On or about the tenth postoperative day the majority of patients had an insulin test meal, but in older patients and those with a history of coronary artery disease this test was omitted.

Annual follow-up was conducted by a physician with no knowledge of which drainage procedure had been used. Particular attention was paid to clinical well-being, evidence of recurrence, diarrhoea, dumping, and bile vomiting. Measurement of weight, haemoglobin, and biochemical data were recorded. Each patient was given an overall clinical grading using a modification of the Visick system:—

---

* Present address: Mark Brown Professor of Medicine, University of Cincinnati, Cincinnati, Ohio, U.S.A.

1. No symptoms: a perfect result.
2. Mild symptoms: not troublesome.
3. More severe symptoms: some degree of disability.
4. Severe symptoms: disabling side-effects, recurrent ulcer, or reoperation.

In assessing episodic diarrhoea and dumping, mild symptoms were graded +, and moderate and severe symptoms + +.

Table I.—DETAILS OF FOLLOW-UP AT 2–5 YEARS

TYPE OF DRAINAGE PROCEDURE	TOTAL AT ENTRY	DIED*	LOST	INTERVIEWED	QUESTIONNAIRE	AVAILABLE FOR STUDY	MEAN FOLLOW-UP TIME (yr.)
Gastrojejunostomy	50	1	1	37	11	48	3·6
Pyloroplasty	50	2	2	43	3	46	3·5
Total	100	3	3	80	14	94	3·55

* Two further deaths occurred in the fourth year

Table II.—CLINICAL STATUS

TYPE OF DRAINAGE PROCEDURE	NO. OF CASES	VISICK GRADING				RECURRENT ULCERATION		
		1	2	3	4	Suspected	Proven	Total
Gastrojejunostomy	48	26	18	1	3	1	1	2
Pyloroplasty	46	24	16	3	3	1	2	3

For Visick grading, $P = 1·00$ For recurrent ulceration, $P = 0·8043$

Table III.—DUMPING

TYPE OF DRAINAGE PROCEDURE	NO. OF CASES	DUMPING		
		+	++	Total
Gastrojejunostomy	48	10	2	12
Pyloroplasty	46	14	4	18

$P = 0·1851$.

The two groups were comparable so far as age and sex were concerned. In the gastrojejunostomy group the mean age was 46·1 years and there were 10 women; in the pyloroplasty group the mean age was 45·8 years and there were 11 women. Ninety-five of the operations were performed by either T. K. or G. W. J. and the remainder by assistants under our direct supervision. Insulin tests on or about the tenth day were performed in 44 gastrojejunostomy patients, 4 giving a positive result by Hollander's criteria; of 42 tests in the pyloroplasty group, 3 were positive.

All 100 patients who entered the trial survived the operation and left hospital, but 5 have subsequently died, 3 during the first 2 years and 2 during the fourth year. The cause of death was not known in every case but none was thought to be directly related to the operation. Three further cases have been lost to follow-up, leaving 48 patients in the gastrojejunostomy group and 46 in the pyloroplasty group available for study. The duration of follow-up was from 2 to 5 years, with a mean of 3·6 years in the gastrojejunostomy group and 3·5 years in the pyloroplasty group (*Table I*). In 11 of the gastrojejunostomy group and 3 of the pyloroplasty group we had to rely on a postal questionnaire as the patients were not available for further interview at 3–5 years.

RESULTS

Clinical Grading.—Each patient was seen initially by A. M. C. and later by either A. H. G. L. or E. F. A. S., who gave him or her a Visick grading according to our modified scheme. Even in the instances where a postal questionnaire was used the majority of patients had had a previous personal interview. Grading was decided by the physicians in consultation. The results (*Table II*) seem to favour gastrojejunostomy marginally; there were more successes (grades 1 and 2) amongst the gastrojejunostomy cases and more failures (grades 3 and 4) amongst the pyloroplasty cases, but the difference did not reach statistical significance. The main cause of failure was suspected or proven recurrence, but 1 case in each group achieved a grade 4 rating because of reoperation for malfunction of the pyloroplasty or gastrojejunostomy respectively; in neither patient was there any operative evidence of recurrence.

Recurrent Ulcer.—In the gastrojejunostomy group there was 1 suspected and 1 proven recurrent ulcer compared with 1 suspected and 2 proven recurrences in the pyloroplasty group (*Table II*), giving an overall probable recurrence rate at 3½ years of 5·1 per cent.

Dumping.—In this series dumping is defined as a feeling of epigastric fullness or discomfort, of weakness, with sweating and palpitations, and often the need to lie down, coming on within half to three-quarters of an hour after a meal, however small.

These symptoms were often not complained of spontaneously but only revealed by close questioning and were seldom a significant nuisance to the patient. There was more dumping after pyloroplasty, but the result was not statistically significant (*Table III*). The occurrence of 6 moderate or severe cases in the whole series was disquieting.

Bowel Habit.—Episodic diarrhoea, which is intermittent, watery, urgent, and sometimes with incontinence, can be a real disability even with only two episodes per attack, since fear of incontinence may dominate the patient's reactions. There were more mild cases amongst the gastrojejunostomy group (*Table IV*), but only 1 moderate/severe (+ +) case in this group compared with 2 in the pyloroplasty group. In 1 of the latter patients severe diarrhoea was attributed to malfunction of the pyloroplasty. At a second operation gastrojejunostomy was added but improvement was only slight.

The frequency of defaecation before and after operation, excluding episodes of diarrhoea, was also studied. There was an increase in the number of motions in each group; the mean increase of 3·1 motions per patient per week in the pyloroplasty group was significantly greater than the mean increase of 1·1 motions in the gastrojejunostomy group (*Table IV*).

Table IV.—ALTERATION IN BOWEL HABIT

TYPE OF DRAINAGE PROCEDURE	NO. OF CASES	EPISODIC DIARRHOEA		INCREASED FREQUENCY OF DEFAECATION (No. per wk.)
		+	++	
Gastrojejunostomy	48	4	1	1·1
Pyloroplasty	46	1	2	3·1

For episodic diarrhoea, $P = 0·7147$. For increased frequency of defaecation, $0·05 > P > 0·02$.

Table VI.—WEIGHT AND BLOOD CHANGES

TYPE OF DRAINAGE PROCEDURE	INCREASE IN WEIGHT (kg.)	MEAN HAEMOGLOBIN (g. per cent)	MEAN CALCIUM (mg. per cent)	MEAN ALKALINE PHOSPHATASE (K.A. units)
Gastrojejunostomy	2 1	14·01	9 4	10·8
Pyloroplasty	1·6	14·05	9·7	9 4

Bilious Vomiting.—Since this symptom has been particularly associated with the operation of gastrojejunostomy, it was looked for very carefully but no difference was found between the two groups (*Table V*). However, there was 1 patient in the gastrojejunostomy group in whom the bile regurgitation and vomiting, with associated gastritis and oesophagitis, were sufficiently severe to require reoperation with closure of the gastrojejunostomy. In 2 patients in each group vomiting of food also occurred from time to time, but this was not considered to be an important problem.

Miscellaneous Symptoms.—Nausea, heartburn, flatulence, and dysphagia (*Table V*) occurred in small numbers in each group, and there was no apparent difference in incidence. It was difficult to categorize these minor symptoms as there was considerable overlap; for example, patients with bile vomiting often complained also of nausea or heartburn.

In other prospective studies of vagotomy that we have conducted, flatulence as an isolated symptom, not associated with dumping or other symptoms, occurred sufficiently often to attract attention. Like Goligher and Pulvertaft (1969) we noted a higher incidence with pyloroplasty.

Evidence of the development of gall-stones was sought in this study, and 2 patients from the gastrojejunostomy group came to cholecystectomy at 2 and 3 years after vagotomy respectively. We cannot be absolutely certain that these patients had no stones at the time of vagotomy, but it is unlikely as the gall-bladder was carefully inspected and palpated in every case.

Nutrition.—There was an overall tendency to gain weight in both groups, the mean gain being 2·1 kg. in the gastrojejunostomy group and 1·6 kg. in the pyloroplasty group (*Table VI*). This is not a significant difference. Haemoglobin levels were available for 41 pyloroplasty patients and 34 gastrojejunostomy patients. Blood and biochemical results could not be obtained from the patients answering postal questionnaires and some patients who were interviewed in their own homes. No difference was found in the haemoglobin levels, a mean of over 14·0 g. being perfectly satisfactory. There were, however, mild degrees of anaemia (between 11·0 and 12·0 g.) in 2 gastrojejunostomy patients and 3 pyloroplasty patients. The same 75 patients had measurements of mean corpuscular volume but no gross macrocytosis was discovered.

Table V.—UPPER GASTRO-INTESTINAL COMPLAINTS

TYPE OF DRAINAGE PROCEDURE	NO. OF CASES	VOMITING BILE	VOMITING FOOD	FLATULENCE	NAUSEA	HEARTBURN	DYSPHAGIA
Gastrojejunostomy	48	5	2	5	9	2	2
Pyloroplasty	46	4	2	9	8	4	0

Serum-calcium levels were also recorded, a slightly higher mean level being found in the pyloroplasty group. No patient had hypercalcaemia but 1 patient in the gastrojejunostomy group had a level of 8·4 mg. per cent, the only one in either group to fall below our lower limit of normal. Alkaline-phosphatase levels were marginally higher in the gastrojejunostomy group and could perhaps have been related to the slightly lower calcium levels (*Table VI*).

DISCUSSION

If a comparison is to be made between pyloroplasty and gastrojejunostomy it is important that each procedure should be fully standardized and that in each case the same type of vagotomy should be used. Of the many variants of pyloroplasty, we chose a modification of the Finney procedure as this is easy to perform and applicable in practically every case, even with severe duodenal stenosis, the only variation being in the length of the initial pyloroduodenal incision. The gastrojejunostomy was also standardized, the objects being to drain the antrum and to leave as short an afferent loop as possible in the hope that bile stasis and regurgitation would thus be minimized. In order to achieve maximal uniformity we limited the trial to a single surgical team.

This trial must obviously be compared with the much larger trial reported by Kennedy and others

(1973) from Glasgow, in which 83 per cent of 404 patients operated on by no less than 45 different surgeons were reviewed. Our numbers are much smaller but in planning this trial we decided to sacrifice numbers for uniformity, and we felt that there were too many questions to be answered by a prospective controlled trial for us to spend more than about 2 years collecting the patients for any one trial. Perhaps because of the smaller numbers involved we have managed to reduce our 'lost' patients to only 3 per cent.

The completeness of our follow-up by interview has been somewhat disappointing, as personal interview conducted on a blind basis is undoubtedly the only entirely satisfactory way of assessing results where so many symptoms are subjective and where there are so few objective measurements. However, in the socio-political climate in which our patients live it was difficult to persuade those without significant symptoms to make hospital visits. Because of this, many patients had to be interviewed in their own homes and in 14 instances we have been forced to rely on postal questionnaires for the 3–5-year follow-up, although most of these patients had been interviewed at an earlier review. Nevertheless, we feel that the data presented here on 94 patients in this trial are valid and comparable.

The incidence of all side-effects is remarkably similar, though the gastrojejunostomy group emerges with a slightly better Visick grading and most symptoms are a little more frequent in the pyloroplasty group. Dumping is slightly more common after pyloroplasty, where a 9 per cent incidence of moderate or severe symptoms was worrying. Evidence from a previous trial suggests that dumping may be more common after selective vagotomy than it is after the truncal operation (*see* p. 944 of this Journal). Sawyers, Scott, Edwards, Shull, and Law (1968) had a similar experience. We have also noted that the incidence and severity of dumping had decreased markedly by the fifth postoperative year, probably as a result of the patients learning to avoid provocative foods and drinks.

The incidence of mild and moderate episodic diarrhoea in the two groups is not enough to cause comment. Kennedy and others (1973) found no difference in the incidence of diarrhoea in their trial. The significantly greater increase of bowel frequency in the pyloroplasty group is interesting, but there is no obvious explanation. It was not necessarily a disadvantage, many patients being delighted by the relief of long-standing constipation.

Bilious vomiting is the one symptom which has been firmly attributed to gastrojejunostomy, but we found no difference in the incidence in our two groups. The only severe case came from the gastrojejunostomy group and a second operation was performed with closure of the gastrojejunostomy. The reversibility of gastrojejunostomy is considered to be a strong point in its favour; we do not believe that it is possible to restore the pylorus after a pyloroplasty. The Glasgow trial showed a significantly higher incidence of bilious vomiting after gastrojejunostomy, but it may be important that the gastrojejunostomy used differed from ours in two important respects. First, in the Glasgow series the anastomosis was made at the most dependent part of the stomach, whereas ours was much closer to the pylorus; secondly, the afferent jejunal loop in our series was very much shorter. In addition, the pyloroplasty used in the Glasgow trial was of the Heineke-Mikulicz type.

Recurrent ulcer might be expected more commonly after pyloroplasty judging by the experience of Goligher, Pulvertaft, Irvin, Johnston, Walker, Hall, Willson-Pepper, and Matheson (1972), who had almost twice as many suspected and proven recurrences after pyloroplasty and truncal vagotomy as after gastrojejunostomy and truncal vagotomy. The 5 recurrences (suspected and proven) in the present series do not show a difference between the groups. More recurrences may appear in the future, though Fawcett, Johnston, and Duthie (1969) found that 75 per cent of recurrences after vagotomy and drainage appeared within the first year.

There is no pattern in the frequency of miscellaneous symptoms favouring either operation. Many of these minor symptoms occur in association with more troublesome symptoms, such as bile vomiting or diarrhoea. The only one which often occurs alone is flatulence and this was a little more frequent after pyloroplasty.

When objective measurements are considered, it seems that weight-gain was not significantly different in the two groups, but it must be recognized that gain of weight is not a good measure of clinical success. In an unpublished study we have found a negative correlation between weight-gain and improvement of Visick grading. There was no difference in the haemoglobin levels, and the striking feature was the absence of severe anaemia and the small incidence of trivial anaemia in the two groups. Wheldon, Venables, and Johnston (1970) reported a high incidence of anaemia 15 years after truncal vagotomy and gastrojejunostomy. Wastell's findings reported in 1969 were similar, with less anaemia after pyloroplasty. This particular point must obviously be re-examined at a later follow-up. There was no evidence of impending macrocytic anaemia, but this may yet become a problem after longer follow-up. Metabolic bone disease has not been a common reported problem after vagotomy and drainage, and we have found no evidence of it though it could also appear in later years.

At 3½-year follow-up there is very little to choose between gastrojejunostomy and pyloroplasty. The former has a marginally better Visick status, possibly a lower rate of recurrent ulcer, less dumping, less increase of bowel frequency, less flatulence, and more weight-gain, but the only one of these differences which is significant is the change of bowel habit. Pyloroplasty, on the other hand, is favoured by marginally less episodic diarrhoea, slightly less bilious vomiting and dysphagia, and a higher level of serum calcium. The overall balance of advantages appears to lie with gastrojejunostomy. When the reversibility of the primary operation is considered the choice becomes easier. Pyloroplasty is irreversible and surgeons are learning to appreciate the importance of conserving this beautiful mechanism. Gastrojejunostomy, however, is readily closed. In 4 cases outside this trial we have closed the stoma, even with truncal vagotomy, and have had no emptying problems. Although the early vagotomies without drainage failed as a group, it is important to remember that at least half of them remained well in the long term. In another study (*see* p. 944 of this Journal) we found that selective vagotomy was superior to truncal vagotomy when each was combined with pyloroplasty. From the results of this trial, using selective vagotomy as the standard procedure, we must conclude that gastrojejunostomy is a better drainage procedure than pyloroplasty.

DRILL BIOPSY OF THE BREAST—A CRITICAL ANALYSIS*

BY J. ST. C. McCORMICK AND A. A. SHIVAS
CHALMERS HOSPITAL AND ROYAL INFIRMARY OF EDINBURGH

SUMMARY

In a study of drill biopsy carried out in 106 patients with breast lesions, comparing the accuracy of diagnosis with that of clinical examination and excision biopsy, reliability declined as stromal reaction in the tumour increased. Accordingly, a negative result is meaningless. Tumour size did not appear to be an important factor. The significance of these results is briefly discussed.

DEFINITIVE treatment of breast lesions rests upon accurate histological diagnosis, and excision biopsy under a general anaesthetic is universally accepted for this purpose.

In such an easily accessible organ it is not surprising, however, that out-patient procedures, such as needle and drill biopsy under local anaesthetic, with potential advantage to both patient and surgeon, have been described. Drill biopsy, although requiring more specialized equipment, is preferable in that it provides a 'core' of tissue showing architectural features of the tumour as well as the cytology, which alone is shown by needle aspiration.

Kirschner (1935) first described a method of drill biopsy in various tissues using a cylindrical cutting needle and dental drill. Ellis advocated the method again in 1947, and in 1960 Deeley described the use of a high-speed pneumatic drill. Subsequently several workers have discussed its use in biopsy of many tissues, notably lymph-glands (Paine, 1969), tumours of the breast (Burn, 1971), lung, pleura (Steel, 1972), and bone (Deeley, 1972).

In an attempt to evaluate the diagnostic accuracy of drill biopsy it was compared with conventional excision biopsy. Throughout the series frozen-section techniques were used to provide an immediate diagnosis; paraffin sections provided a check on histological accuracy in both drill and excision biopsies.

MATERIAL AND METHODS

One hundred and six consecutive patients with breast lesions presenting between January and November, 1972, were examined and a clinical diagnosis was made. The size of the lesion and other relevant features were noted in the usual way.

Under general anaesthesia the tumour was stabilized gently between finger and thumb and a small skin incision was made over it with the point of a knife. A cylindrical hollow needle, 2 mm. in diameter, was fitted to the pneumatic drill with the air pressure above 60 lb. per in.^{2}. The speed of the drill was about 20,000 revolutions per minute and was to some extent adjustable by pressure on the trigger. It was introduced down into the tumour, which was then drilled through. Gentle negative pressure was applied to the needle with a syringe full of saline after dismantling the drill. The contained core of tissue was then either sucked into the syringe or expelled directly on to a saline swab. Excision biopsy of the lesion was carried out in the usual manner and both specimens were submitted for frozen-section examination.

In most patients two drill biopsies were performed through the same incision.

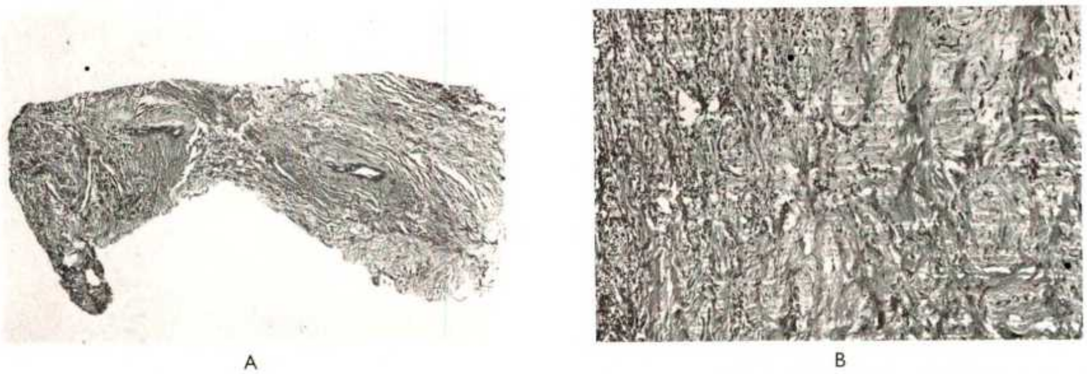
RESULTS

The pathology of the lesions examined is detailed in *Table I*. Included in the carcinoma group were 1 mucoid, 1 squamous, and 1 intraduct carcinoma. There were 2 medullary and 1 male breast carcinoma.

---

* Presented to the Royal Society of Medicine, 21 Feb., 1973.

Carcinomas.—The diagnostic accuracy of clinical examination, drill biopsy, and frozen-section excision biopsy is compared in *Table II*. Drill biopsy is the least accurate, but excision biopsy and clinical examination both missed carcinomas. Those missed clinically were all 2·5 cm. or less in size. The false negative occurring with excision biopsy was discovered because of continuing clinical suspicion. The patient was readmitted for further biopsy and subsequent mastectomy 6 weeks later.



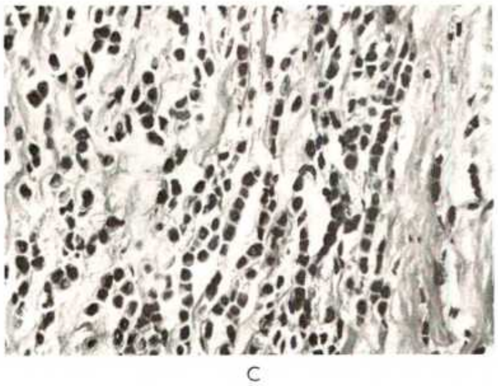


FIG. 1.—A, Drill biopsy showing ducts and dense fibrous tissue. A few cells of doubtful histogenesis are included but there is no valid evidence of tumour growth. H. and E. (× 56.) B, Excision biopsy from the same lesion. The tumour shows marked stromal reaction; only on the left of the field is there overt infiltration by carcinoma. It is obvious that a sample obtained by drill biopsy can readily prove uninformative. H. and E. (× 60.) C, High-power examination shows clearly the neoplastic nature of the infiltrate in the left field of B. H. and E. (× 266.)

Table I.—PATHOLOGY OF ALL THE LESIONS EXAMINED BY DRILL BIOPSY OF THE BREAST (106 PATIENTS)

Pathology	*No. of Cases*
Carcinoma	40
Fibro-adenosis	45
Solitary cyst	11
Fibro-adenoma	4
Fat necrosis	3
Cystosarcoma phylloides	1
Acute mastitis of pregnancy	1
Florid papilloma	1

Benign Lesions.—The three methods of diagnosis are again compared in *Table III* in respect of benign pathology. In 14 cases in the drill-biopsy group the histology, although benign, was not representative of the lesion subsequently excised; this group included 11 solitary cysts which were aspirated, but only fragmentary tissue for histology was obtained: 2 of these cysts were misinterpreted as carcinoma clinically.

The case of cystosarcoma phylloides could have been misinterpreted as malignant on the drill-biopsy specimen; this was thought to be true also of a biopsy of fibro-adenosis with marked epitheliosis.

The doubtful false positive on excision biopsy was a florid papilloma, diagnosed as an early intraduct carcinoma, but not confirmed on paraffin section.

Table II.—ACCURACY OF DIAGNOSTIC METHODS IN CARCINOMA OF THE BREAST (40 PATIENTS)

Diagnostic Method	*Correct Diagnosis*	*False Negative*
Clinical	37	3
Drill biopsy	30	10
Excision biopsy	39	1

Table III.—ACCURACY OF DIAGNOSTIC METHODS IN BENIGN BREAST LESIONS (66 PATIENTS)

Diagnostic Method	*Correct Diagnosis*	*False Positive*
Clinical	64	2
Drill biopsy	64	2 doubtful
Excision biopsy	65	1 doubtful

Table IV.—ACCURACY OF DRILL BIOPSY IN RELATION TO TUMOUR SIZE IN CARCINOMA OF THE BREAST (40 PATIENTS)

	TUMOUR SIZE		
	2 cm. or less	2·5–5 cm.	6 cm. or more
No. of carcinomas	15	17	8
False negatives	4	3	3

Tumour Size.—Comparing tumour size and accuracy of drill biopsy (*Table IV*), this series does not suggest any direct relationship. Early in the series the impression was gained that false negatives were more frequent among the smaller tumours, and this is the experience of others (Burn, 1971).

Stromal Reaction.—In an attempt to investigate the cause of inaccuracy further the tumours were classified according to the stromal reaction which they evoked histologically (*Table V*). It is appreciated that stromal reaction may vary greatly from field to field in any one tumour; nevertheless, it is a semi-quantitative characteristic of breast carcinoma which has broad general validity.

Tumours with marked stromal reaction are associated with a greater number of false-negative results on drill biopsy. It is likely that the core from a drill biopsy in this group will have a high proportion of stromal elements to tumour cells, the latter being often insufficient to give a definitive diagnosis by any method (*Fig.* 1). Some such biopsies were reported as suspicious but not diagnostic. Trauma is a further contributory factor to inaccuracy, sometimes preventing definitive diagnosis (*Fig.* 2). *Fig.* 3 illustrates a tumour having minimal stromal reaction, and a diagnostic drill biopsy was consequently obtained.

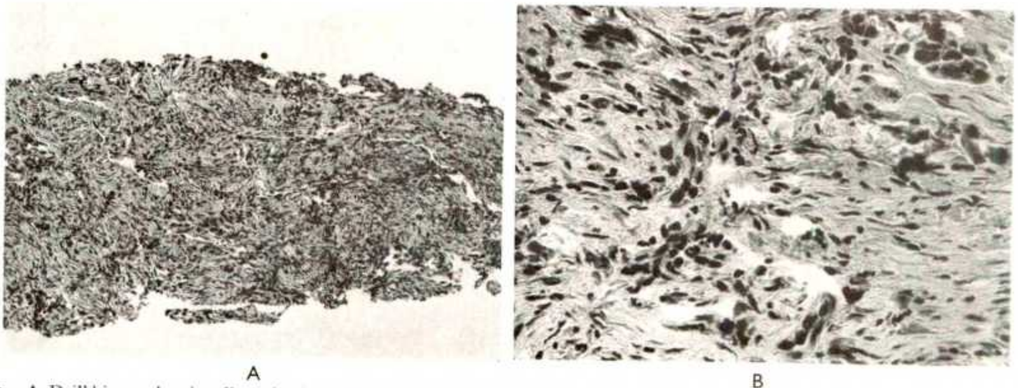

FIG. 2.—A, Drill biopsy showing distortion by trauma, producing a pseudofasciculation and suggesting a connective-tissue lesion. H. and E. (× 66.) B, High-power examination is more suggestive of an infiltration but its precise nature remains in doubt. H. and E. (× 266.)

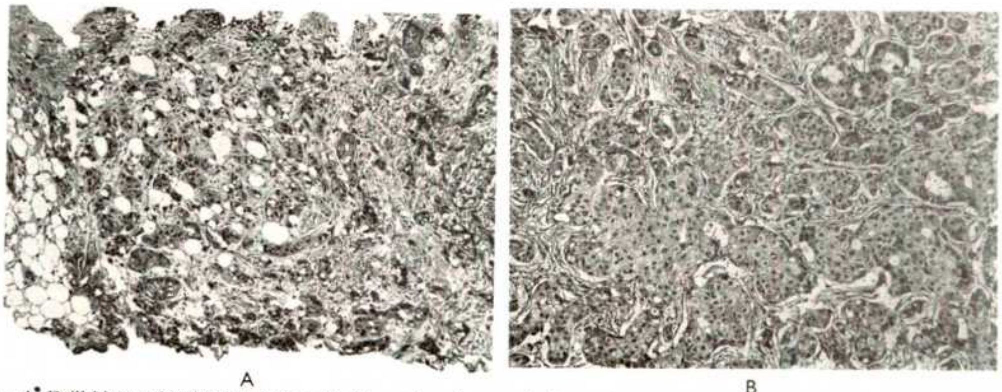

FIG. 3.—A, Drill biopsy showing infiltration of adipose tissue by anaplastic carcinoma. H. and E. (× 60.) B, Excision biopsy from the same lesion. The minimal stromal reaction assures an informative drill biopsy and a definitive diagnosis. H. and E. (× 60.)

Table V.—ACCURACY OF DRILL BIOPSY IN RELATION TO STROMAL REACTION IN CARCINOMA OF THE BREAST (40 PATIENTS)

Stromal Reaction	*Correct Diagnosis*	*False Negatives*
Nil	5	1
Mild	14	0
Moderate	10	2
Marked	11	7

The overall accuracy is expressed as a percentage in *Table VI*. The clinical accuracy compares favourably with that of other series (Gravelle, 1969, 88·1 per cent; Strax, Venet, Shapiro, Gross, and Venet, 1971, 77 per cent). The accuracy of excision biopsy in this series also compares favourably with that of Sparkman (1962, 97·7 per cent). Drill biopsy in the present series was not as accurate as the 95 per cent rate of Burn (1971) and the 90 per cent of Ellis (1947), but compares well with the 70 per cent of Paine (1969); in our series, however, frozen-section methods were used to give an immediate answer.

Table VI.—OVERALL ACCURACY OF DRILL BIOPSY OF THE BREAST (106 PATIENTS)

DIAGNOSTIC METHOD	CORRECT DIAGNOSIS	
	No.	Percentage
Clinical	101	95
Drill biopsy	92	84
Excision biopsy	104	98

DISCUSSION

Drill biopsy combined with frozen section may give an immediate definitive diagnosis of carcinoma and can be used as an out-patient procedure. The clinician can then discuss the diagnosis with the patient and her subsequent treatment with added confidence. In addition, the urgency of the situation can be judged more accurately for admission purposes and subsequent investigations planned more effectively. For example, bone scans with radionuclides are often used as an adjunct to clinical tumour staging to determine whether curative or palliative therapy is indicated, and histological proof is desirable in patients in their reproductive years. Unnecessary referral to radiotherapy departments might also be avoided; the surgeon could proceed to mastectomy without further biopsy, thus minimizing contamination of the operative field.

Potential disadvantages of the method may be local seeding of the tumour from the biopsy track and this has been reported with needle biopsy (Godwin, 1956); to date it has not been found in drill biopsy (Steel and Winstanley, 1967). The danger of contributing to further metastases has also been investigated by Burn, Deeley, and Malakar (1968) using the Walker 256 tumour in rats; no increased evidence of metastasis was found in rats submitted to drill biopsy.

The accuracy of our series is disappointing, especially compared with needle-aspiration cytology which is claimed by Webb (1970) to be 97·3 per cent accurate. With the latter method experience has been shown to improve the results (Adair, 1949), but it is difficult to believe that this would be true of drill biopsy if the findings relating to stromal reaction are significant—about 25 per cent of carcinomas will have marked stromal reaction and the proportion of stromal tissue to tumour elements will remain high. Under these circumstances chance is likely to play a greater part than skill in providing the correct diagnosis. Sampling error can therefore be very great and a negative result is quite meaningless.

It is worth noting that a wide experience of biopsies of similar size and nature, e.g., bronchial biopsies, has demonstrated that there are no special difficulties of interpretation peculiar to the frozen-section method.

It is concluded from this study that while drill biopsy with frozen section has many potential advantages it is of insufficient accuracy to supersede excision biopsy. The biological nature of the tumour (rather than its size or the skill of the surgeon) may be the reason for the difficulties encountered.

Acknowledgements.—Patients in this series were under the care of Mr. T. J. McNair and Mr. J. W. W. Thomson, and we are grateful to them for their encouragement and advice. We would also like to thank Mr. Ian Burn for introducing us to the technique.

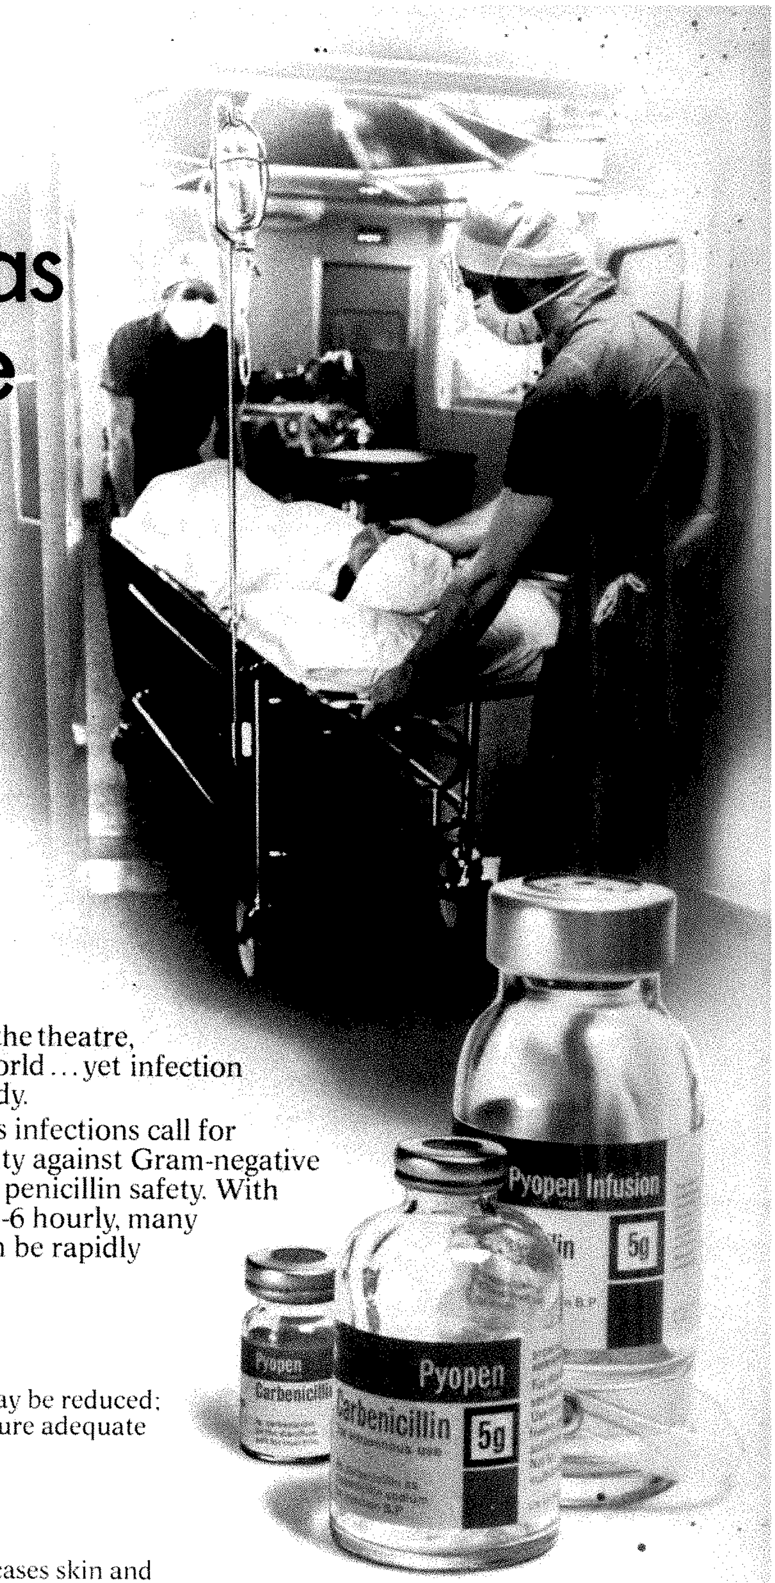
When pseudomonas threatens the success of surgery



Pyopen

The skill of the surgical team, hours in the theatre, the most advanced techniques in the world . . . yet infection can still throw the outcome into jeopardy.

Post-operative pseudomonas or proteus infections call for Pyopen. Only Pyopen offers good activity against Gram-negative organisms with the added advantage of penicillin safety. With intravenous Pyopen, at a dosage of 5g 4-6 hourly, many dangerous post-operative infections can be rapidly controlled.

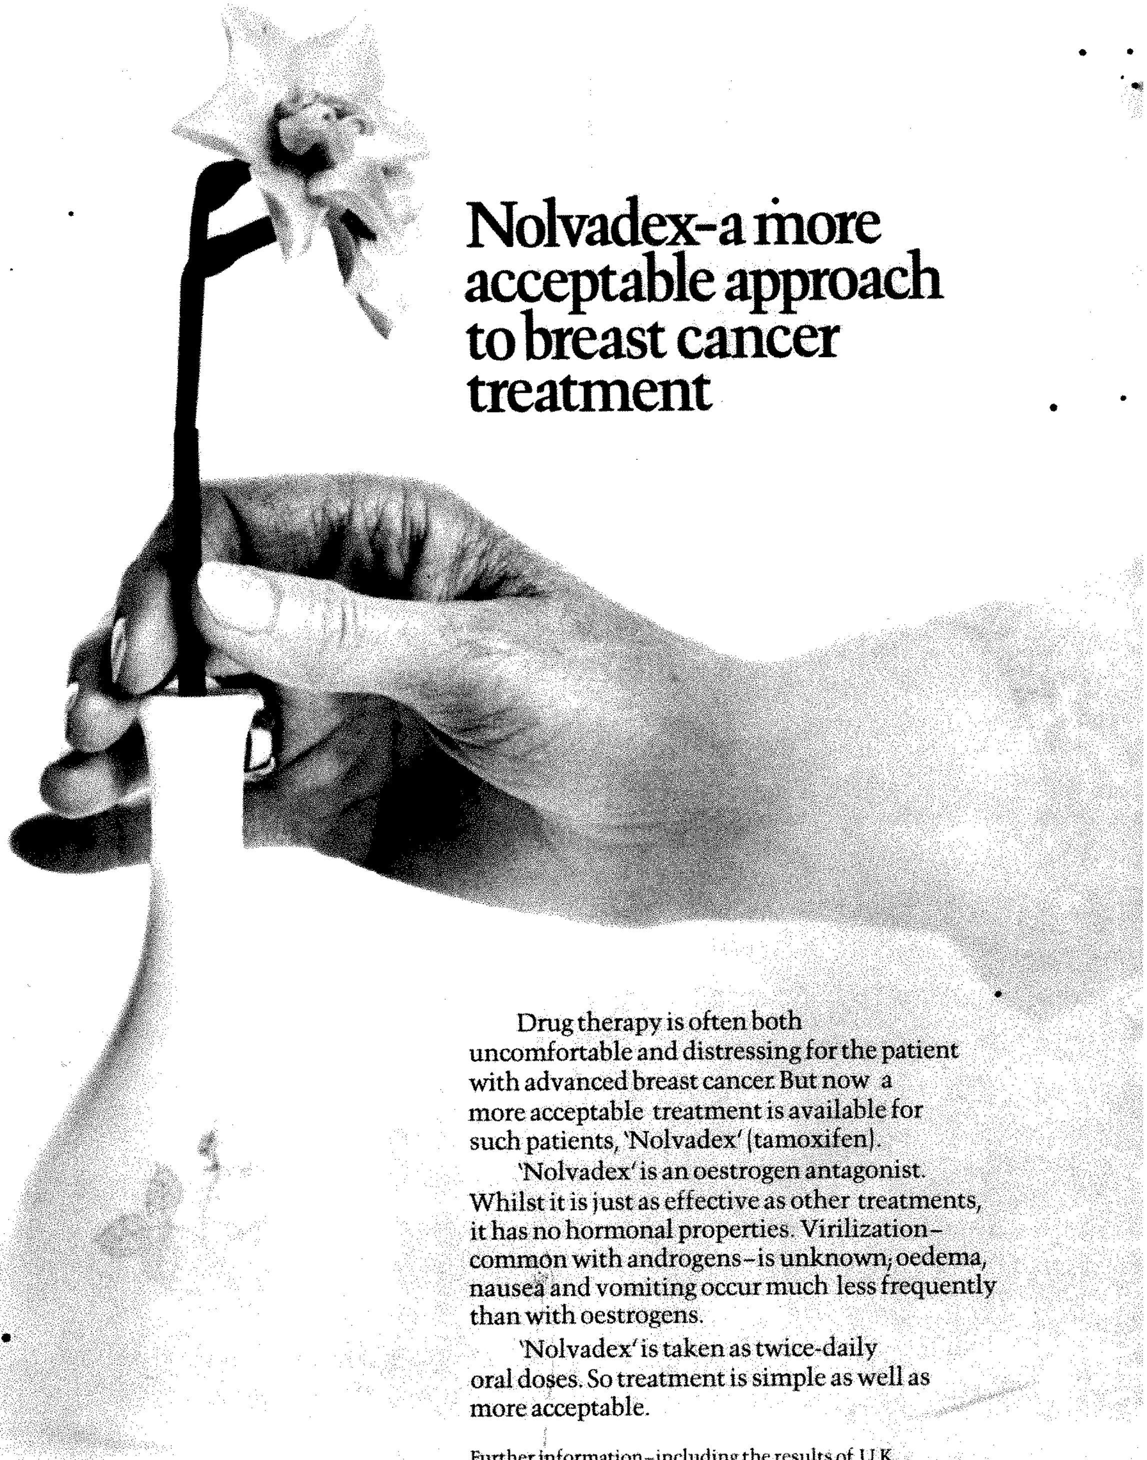
Adult Dosage
5g I.V. 4-6 hourly.
In patients with renal impairment dosage may be reduced; monitoring is advisable in these cases to ensure adequate serum antibiotic levels.

Contra-indication
Penicillin hypersensitivity.

Side-effects
As with other injectable penicillins. In rare cases skin and mucous membrane haemorrhages due to interference with normal clotting mechanisms have been reported.

Pyopen-by infusion or injection

Further information is available on request.
Pyopen* (carbenicillin sodium B.P.) is a British product originated by
Beecham Research Laboratories, Brentford, England. *regd.



Nolvadex–a more acceptable approach to breast cancer treatment

Drug therapy is often both uncomfortable and distressing for the patient with advanced breast cancer. But now a more acceptable treatment is available for such patients, 'Nolvadex' (tamoxifen).

'Nolvadex' is an oestrogen antagonist. Whilst it is just as effective as other treatments, it has no hormonal properties. Virilization–common with androgens–is unknown; oedema, nausea and vomiting occur much less frequently than with oestrogens.

'Nolvadex' is taken as twice-daily oral doses. So treatment is simple as well as more acceptable.

Further information–including the results of U.K. trials with 'Nolvadex'[1,2] is available on request.

THE PROBLEM OF LOCAL RECURRENCE FOLLOWING CONSERVATIVE SURGERY FOR CARCINOMA OF THE BREAST

By M. E. BAILEY, K. RATNAVEL, and A. P. WYATT
ST. JAMES'S HOSPITAL, LONDON

SUMMARY

Follow-up of patients after local excision of carcinoma of the breast indicated that there was a high incidence of local recurrence and that this could be a difficult problem to manage. A retrospective study was performed comparing 50 patients who had undergone local excision and radiotherapy with 50 patients following simple mastectomy and radiotherapy. Local recurrence occurred in 16 per cent of the local excision group compared with 2 per cent in the simple mastectomy group.

MATERIALS AND METHODS

Forty-six patients with clinical stage I and 4 patients with clinical stage II carcinoma of the breast underwent local excision of the tumour and postoperative radiotherapy (group 1) between the years 1960 and 1969. These were compared with 50 patients treated during the same period by simple mastectomy and radiotherapy (group 2). They were matched for age, time of operation, and clinical stage of the carcinoma. The follow-up varied from 18 months to 18 years. All the patients were interviewed and examined and any local or systemic recurrence was recorded. Local recurrence was defined as that occurring in the treated area of the chest wall (Haagensen, Cooley, Miller, and others, 1969) and included any recurrence in the residual breast tissue.

Table I.—Results of Local Excision and Radiotherapy compared with Those of Simple Mastectomy and Radiotherapy for Carcinoma of the Breast

Type of Recurrence	Local Excision and Radiotherapy (50 patients)		Simple Mastectomy and Radiotherapy (50 patients)	
	No.	Per cent	No.	Per cent
Local	8	16	1	2
Distant	16	32	12	24
Combined local and distant	3	6	1	2
Local but no distant	5	10	0	
Overall mortality	14	28	9	18

RESULTS

The mean age of the patients in the local excision group was 56·3 years and in the simple mastectomy group 55·9 years, the greatest age difference being 6 years. On average the local excisions were performed 22·5 days later than the mastectomies. The mean length of follow-up was 5·2 years.

Recurrence within the treated area occurred in 8 out of 50 patients (16 per cent) treated by local excision and radiotherapy, and in 1 out of 50 patients (2 per cent) treated by simple mastectomy and radiotherapy; 16 patients in the first group (32 per cent) and 12 in the second group (24 per cent) developed distant metastases (*Table I*). The number of patients with both local and distant recurrences in group 1 was 3 (60 per cent) and in group 2 was 1 (2 per cent). Therefore there were 5 patients (10 per cent) in group 1 who had local recurrence without evidence of systemic recurrence. The overall mortality in group 1 was 14 out of 50 (28 per cent) and in group 2 was 9 out of 50 (18 per cent).

DISCUSSION

This study is a retrospective one and suffers from all the limitations and disadvantages of any such study. However, much has been written concerning the type and extent of treatments for carcinoma of the breast in terms of survival rates (McWhirter, 1955; Peters, 1967; Haagensen and Cooley, 1969; Handley and Thackray, 1969; Kaae and Johansen, 1969; Miller, 1969), but less emphasis has previously been given to local recurrence following conservative surgery (Mustakallio, 1954; Porritt, 1964; Crile, 1965; Crile and Hoerr, 1971; Taylor, Baker, Fortt, and Hermon-Taylor, 1971; Atkins, Hayward, Klugman, and Wayte, 1972).

Mustakallio (1954) reported 127 patients with stage I lesions 'no bigger than a hen's egg' treated by local excision and radiotherapy. The local recurrence rate was not stated but 3 patients did subsequently require radical mastectomy for this. He also stated that if local recurrence was present distant metastases were 'simultaneously or almost simultaneously to be found'. In 10 per cent of our patients this was not the case. Mustakallio found that 'it also appeared that local metastases could be controlled or cured with roentgen therapy'.

Porritt (1964) reported 85 per cent 5-year survival 'in early cases' treated by local excision and radiotherapy and a 22 per cent survival 'in late cases' similarly treated. The 10-year survivals were 70 per cent and 30 per cent respectively. These rates compared favourably with those in cases treated by radical mastectomy and radiotherapy but no mention was made of local recurrence following either type of procedure.

Crile (1965) recorded a 65 per cent 5-year survival following local excision and radiotherapy and a local recurrence rate in clinical stage I lesions of 1 in 12 (8·33 per cent). In stage II lesions the local recurrence was 4 out of 8 (50 per cent). No mention was made of their subsequent management.

Crile and Hoerr (1971) reported a 5-year survival rate of 67 per cent in 55 patients treated by local excision, 40 of whom were clinically stage I and 15 stage II; 34 patients were alive without evidence of growth, and 3 were alive with recurrent carcinoma. This compares with a 68 per cent 5-year survival in all operable patients (i.e. 317 out of 465 patients) treated in the same period either by simple mastectomy or modified radical mastectomy with or without radiotherapy. The local recurrence rate in the two groups was 11 per cent after local excision and 8 per cent after mastectomy. There were no recurrent tumours in the breast tissue. Crile states that 'most of the time' the incidence of locally recurrent tumours was controlled satisfactorily by irradiation.

Taylor and others (1971) found a local recurrence rate of 14 out of 77 patients (18 per cent) following sector mastectomy and postoperative radiotherapy; 11 within the first 5 years and 1 after 15 years. They could find no distinctive clinical or pathological features to predict the likelihood or otherwise of local recurrence in any individual case in the series, there being no difference in mean age at diagnosis or size of tumour, but the proportion of stage II lesions (50 per cent), histological grade 3 (14 per cent), and absence of lymphocytic reaction (54 per cent) was higher in the recurrence group.

Atkins and others (1972) described 45 out of 182 patients developing local recurrence following wide excision ('extended tylectomy') and postoperative radiotherapy, compared with 13 out of 188 following radical mastectomy and radiotherapy. From their figures it appears that 26 out of 45 patients in the first group underwent further surgery. It is also worth noting that 31 out of 182 patients who had had extended tylectomies had local recurrence without simultaneous widespread dissemination.

In the series reported here the local excision varied from wide removal of the tumour to segmental excision of the part of the breast containing it. No axillary dissection or node biopsy was performed. All the local recurrences except 1 were in clinical stage I cases, which is contrary to most other series. There was a much higher percentage of local recurrence in the local excision and radiotherapy group compared with the simple mastectomy and radiotherapy group (16 per cent compared with 2 per cent).

Ten per cent of the patients in group 1 had local recurrence without any evidence of distant metastases. In 3 of these patients the local recurrence was extensive by the time of diagnosis, with local cutaneous growth, infection, and, in 1 case, fungation. These presented considerable difficulty in local management since further direct operation was not possible and response to further radiotherapy was poor. Hormonal ablation similarly was ineffective.

Local recurrence may be diagnosed late in such circumstances because of failure of patients to attend for regular follow-up or because of difficulty in differentiation between recurrent growth and post-operative or radiotherapy effects (Williams, Murley, and Curwen, 1953).

It is suggested that there is considerable evidence that the local recurrence rate is higher in patients who have conservative surgery for carcinoma of the breast compared with those who have a more radical operation, and that this can present difficulty in management in a patient who may otherwise be clinically free from disease.

THE EFFECT OF INCREASED OXYGEN IN PROLONGED ACUTE LIMB ISCHAEMIA

BY C. G. STALKER AND I. McA. LEDINGHAM
UNIVERSITY DEPARTMENT OF SURGERY, WESTERN INFIRMARY, GLASGOW

SUMMARY

Prolonged acute hindlimb ischaemia was produced in anaesthetized ventilated dogs. During ischaemia, oxygen extraction and consumption rose initially but later consumption fell towards normal in the least severely ischaemic limbs; a progressive fall to below normal occurred in the most severely ischaemic limbs. Hyperbaric oxygen (2 ATA) did not influence blood-flow or metabolic exchange in either of these groups; in the remaining 40 per cent of the animals blood-flow fell significantly but oxygenation of the perfused areas of the limbs appeared to improve.

HYPERBARIC oxygenation has been used extensively in the treatment of various ischaemic conditions. The method, however, has not realized the initial clinical expectation. One of several possible explanations for this disappointing observation may be the vasoconstrictor effect of hyperoxia which has been described both in normal subjects (Bird and Telfer, 1966) and in patients with peripheral vascular disease (Schraibman and Ledingham, 1969a). Further physiological studies of the relationship between arterial oxygen tension and peripheral ischaemia seem justified.

In a previous experimental study (Stalker, McEwan, and Ledingham, 1973) the authors described the changes in limb blood-flow and oxygen consumption in dogs subjected to a brief period of ischaemia, and showed that the administration of oxygen at 2 ATA was associated with an increase in oxygen availability to the ischaemic limb and in the oxygen tension of the effluent venous blood; no consistent change in oxygen consumption occurred with hyperoxia. The present study reports the effects of more prolonged limb ischaemia on blood-flow and oxygen consumption and the different patterns of response to hyperbaric oxygen during the period of sustained ischaemia.

MATERIALS AND METHODS

Studies were performed on 12 mongrel dogs (weight range, 22–30 kg.) within one of the large compressed air chambers at the Western Infirmary, Glasgow. Anaesthesia was induced with sodium thiopentone (20 mg. per kg.) and maintained with trichlorethylene. Intermittent suxamethonium chloride was given as required to prevent reflex movement. The dogs were intubated and intermittent positive-pressure ventilation was established using a Palmer pump, the stroke volume of which was adjusted to maintain an arterial carbon dioxide tension (Paco$_2$) between 35 and 45 mm. Hg. The inspired oxygen concentration was measured with a paramagnetic oxygen analyser (Servomex DCL 101 Mk II). A catheter inserted in the brachial artery was advanced to lie in the mid-aorta (proximal to the site of subsequent arterial ligation). Arterial blood samples were withdrawn from this site and pressure recordings made using an ink-jet recorder (Elema Schönander Mingograph 81). Limb skin and mid-oesophageal temperatures were recorded on an Ellab TE3 Universal Thermocouple and the latter temperature was maintained constant within ± 1° C.

The canine limb is well supplied with collateral arterial channels. The lower limb vessels were exposed, therefore, at the root of the aorta and ischaemia was produced by ligating the external, internal, and circumflex iliac arteries as well as the median sacral artery. A T-tube was inserted at the level of the groin into the femoral vein and heparin was administered by the intravenous route in a dose of 100 mg. per kg. Blood-flow was measured by first clamping the proximal limb of the T-tube and thereafter collecting the effluent venous blood during exactly 30 or 60 seconds. Blood removed in this fashion was retransfused. The bulk of the blood passing out of the limb traversed the T-tube. Venous pressure was recorded before and after each blood-flow measurement. After initial surgery the animal was allowed to settle for a minimum period of 1 hour.

Table I.—DATA (MEAN ± S.E. OF THE MEAN) IN 12 DOGS BEFORE AND AFTER ARTERIAL LIGATION

	PRE-ISCHAEMIA		EARLY ISCHAEMIA (15 min)		LATE ISCHAEMIA (4 hr.)
Limb blood-flow (ml. per min.)	100 ± 7	$P<0{\cdot}001$	31 ± 3		23 ± 4
Pvo$_2$ (mm. Hg)	71 ± 4	$P<0{\cdot}001$	26 ± 2		30 ± 2
Pvco$_2$ (mm. Hg)	42 ± 2	$P<0{\cdot}001$	60 ± 3	$P<0{\cdot}001$	113 ± 13
O$_2$ availability (ml. per min.)	25·9 ± 2·1	$P<0{\cdot}001$	7·8 ± 0·8		5·6 ± 0·8
O$_2$ extraction (per cent)	6 ± 2	$P<0{\cdot}001$	59 ± 4		65 ± 5
O$_2$ consumption (ml. per min.)	1·1 ± 0·6	$P<0{\cdot}001$	4·7 ± 0·6		3·7 ± 0·6
Excess lactate (mmol per litre)		$P<0{\cdot}001$	1·4 ± 0·2	$P<0{\cdot}005$	6·1 ± 1·2

Mid-aortic and femoral venous blood samples were withdrawn for measurements of oxygen and carbon dioxide tension and *p*H using a triple electrode system (Radiometer Micro Electrode Unit with *p*H-meter 27 and Gas Monitor). Correction for the difference in oxygen-tension measurement between gas and blood was made using tonometered blood (McDowall, Ledingham, and Tindal, 1968). Further correction of the blood-gases and *p*H was made for any temperature difference between the electrode recirculation system and the animal's mid-oesophageal temperature (Radiometer Blood Gas Calculator Type B.G.C.1). Arterial and venous blood was removed for lactate and pyruvate estimations using the method of Boehringer and Sons. Haemoglobin (Hb) and packed-cell volume (P.C.V.) were measured at intervals throughout the experiment. The following data were derived:—

1. *Blood-oxygen content* (ml. per 100 ml.) = Hb (g.) × 1·34 × (O_2 saturation/100) + Po_2 (mm. Hg) × 0·0031 (Bunsen coefficient).

2. *Limb oxygen consumption* (ml. per min.) =

$$\frac{\text{Femoral vein flow (ml. per min.)} \times \text{femoral arteriovenous oxygen content difference (ml. per 100 ml.)}}{100}.$$

3. *Limb oxygen availability* (ml. per min.) =

$$\frac{\text{Femoral vein flow (ml. per min.)} \times \text{arterial oxygen content (ml. per 100 ml.)}}{100}.$$

4. *Limb oxygen extraction* (per cent) =

$$\frac{\text{Femoral arteriovenous oxygen content difference (ml. per 100 ml.)} \times 100}{\text{Arterial oxygen content (ml. per 100 ml.)}}.$$

5. *Excess lactate of the ischaemic limb*, according to the formula:—

$$(L_n - L_0) - (P_n - P_0)(L_0/P_0),$$

where L_0 and P_0 are the initial venous lactate and pyruvate values and L_n and P_n are the subsequent venous lactate and pyruvate values.

After the period of stabilization baseline measurements were recorded and the limb was rendered ischaemic as previously indicated. The initial period of study was performed at normal atmospheric pressure with the inspired gas mixture adjusted to maintain the arterial oxygen tension (Pao_2) between 95 and 105 mm. Hg; this period lasted at least 3 hours. The subsequent stage of each experiment was conducted at 2 ATA with oxygen as the inspired gas (Pao_2, ca. 1100 mm. Hg); this period lasted at least 1½ hours. Previous experiments established that pressure *per se* did not influence blood-flow and metabolism (Stalker and others, 1973).

RESULTS

The data in all 12 dogs before and up to 4 hours after arterial ligation are shown in *Table I*. Arterial ligation was associated with a fall in limb blood-flow on the affected side and a rise in oxygen extraction and oxygen consumption ($\dot{V}O_2$). The femoral venous oxygen tension (Pvo_2) fell by 45 mm. Hg and femoral venous carbon dioxide tension ($Pvco_2$) rose by 18 mm. Hg and continued to rise until at 4 hours the value was 113 ± 13 mm. Hg (mean ± standard error of the mean). Excess lactate showed a similar progressive rise and oxygen availability a progressive fall.

Analysis of the data of the individual dogs demonstrated that sustained arterial ligation resulted in a progressive fall in limb blood-flow in 3 of the dogs while the flow remained stationary in the other 9 (*Fig.* 1). In the 3 animals with a progressive fall in limb blood-flow the latter did not improve on release of the arterial ligatures, and skin temperature and excess lactate were also unaltered. These features along with marked muscle rigidity suggested that the limbs were dying (*Fig.* 2). In contrast, animals with a stable blood-flow exhibited a brisk reactive hyperaemia after release of the ligatures with an associated rise in skin temperature and fall in excess lactate, i.e., the limbs appeared to be surviving (*Fig.* 2).

Subsequent analysis of the experimental data is based on the observed variation in haemodynamic and metabolic response to hyperoxia during sustained ischaemia. Hyperbaric oxygen did not influence blood-flow in the 3 limbs which were judged to be dying (group A) or in 4 of the surviving limbs (group B—non-reactors); in the other 5 surviving limbs (group C—reactors) hyperoxia was associated with a further significant fall in blood-flow in the ischaemic limb ($P < 0·01$).

In all three groups of dogs ligation of the hind-limb arteries produced a substantial fall in blood-flow with parallel changes in oxygen availability (*Fig.* 3). Immediately after ligation blood-flow in the non-reactors exceeded that in the reactors by 9 per cent, but immediately prior to the period of hyperoxia the flows in both groups were comparable and exceeded flow in the dying limbs by 15 per cent. Oxygen extraction in all three groups (*Fig.* 4) rose initially by 53–59 per cent and, in general, the more severe the initial ischaemia the more marked were the changes in extraction. Thereafter, oxygen extraction tended to fall in the 5 animals of group B (non-reactors) and continued to rise in the other two groups, reaching 80 per cent 4½ hours after ligation in the dying limbs (group A). Oxygen consumption in all three groups rose fivefold after ligation and then fell in the animals with the dying limbs and in the surviving non-reactors. The fall in the latter group occurred immediately, but after the third hour flattened out at a level over twice normal. In the dying limbs the fall was delayed but once started became progressive. Oxygen consumption in the surviving reactor limbs did not fall throughout the 3½-hour period of ligation.

Pvo_2 fell to values between 20 and 30 mm. Hg in all three groups (*Fig.* 5), but just prior to the administration of hyperbaric oxygen the value in the surviving non-reactor limbs exceeded that of the other two groups by 10 mm. Hg. $Pvco_2$, having risen initially, plateaued at around 70 mm. Hg in the surviving non-reactor limbs and continued to rise in the other two groups to values of between 140 and 180 mm. Hg. The surviving non-reactor limbs were strikingly different from the other two groups in respect of excess lactate (*Fig.* 6), the level in the former levelling off at below 3 mmol per litre and rising progressively in the latter to between 7 and 11 mmol per litre.

The administration of oxygen at 2 ATA produced only slight transient falls in blood-flow in the dying and surviving non-reactor limbs (*Fig.* 3). In these same groups there was a transient fall in oxygen extraction and a rise in Pv_{O_2} (*Figs.* 4, 5), but the pattern of change in Pv_{CO_2} and in excess lactate was not altered (*Figs.* 5, 6). Oxygen consumption continued to fall in the dying limbs but appeared to rise slightly in the surviving non-reactor limbs. In the surviving reactor limbs, i.e., those demonstrating a significant reduction in blood-flow and oxygen availability ($P < 0{\cdot}01$), there was a sustained fall in oxygen extraction and consumption (*Fig.* 4). Pv_{O_2} and Pv_{CO_2} both rose initially and then levelled off, while excess lactate plateaued immediately and even began to fall.

DISCUSSION

The initial degree of ischaemia induced by arterial ligation in this study was comparable to that reported in the earlier investigation of acute limb ischaemia (Stalker and others, 1973). The curious finding of a disproportionately large increase in oxygen extraction was also confirmed. Thus oxygen consumption, as derived from the product of blood-flow and arterio-venous oxygen content difference, was substantially elevated, although in the majority of animals the initial very high values began to decrease after 1–2 hours of ischaemia and in the severely ischaemic limbs fell below normal after 6–7 hours.

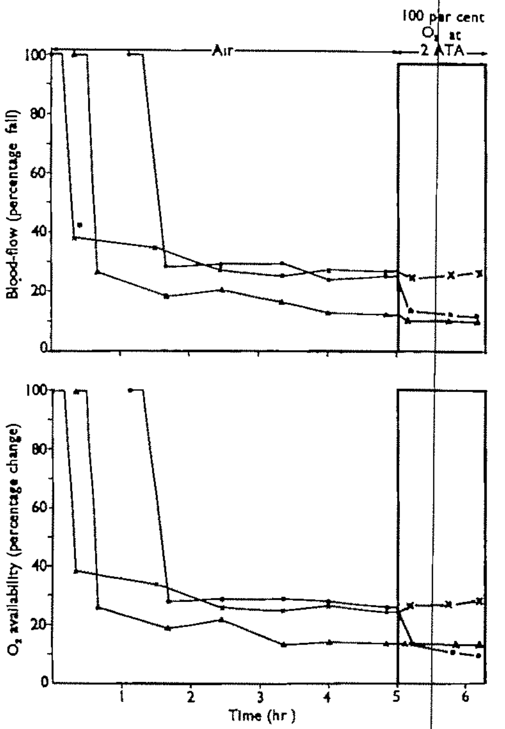

Fig. 3.—Percentage changes in blood-flow and oxygen availability in the three groups: group A, dying (▲); group B, non-reactors (×); group C, reactors (●). In the reactor group oxygen availability was significantly reduced during hyperoxia. The difference between the three groups in duration of ischaemia was calculated in a retrospective fashion from the onset of hyperoxia.

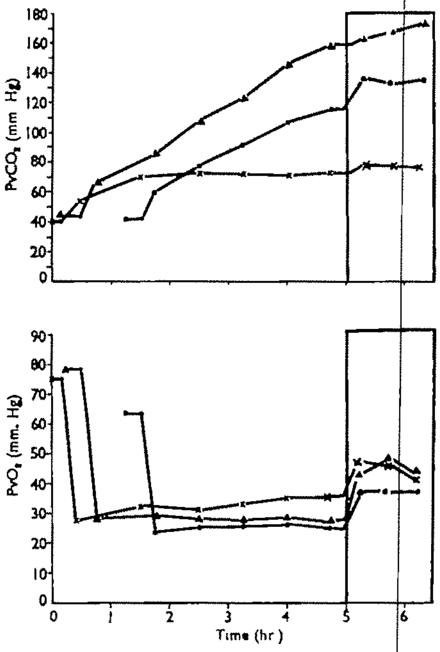

Fig. 5.—Venous P_{CO_2} and P_{O_2} values in the three groups. All groups showed a rise in P_{vO_2} during hyperoxia. P_{vCO_2} rose initially in all animals but flattened out in the non-reactors. Symbols as in *Fig.* 3.

During the course of the present study further steps were taken to eliminate the possibility of an error in experimental technique to explain the oxygen consumption data.

1. Oxygen Content Measurement.—The derived method of measurement of oxygen content was previously validated by comparison with the direct method of Van Slyke. Recently a further comparison between the derived method and a new direct method (Valeri, Zaroulis, Marchionni, and

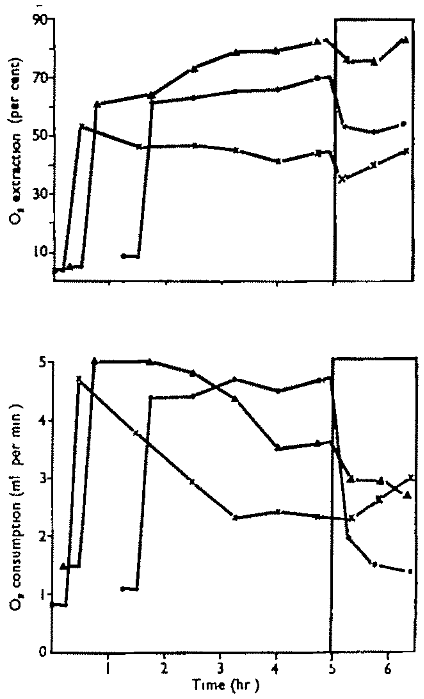

Fig. 4.—Oxygen extraction and consumption in the three groups. The greater the degree of initial ischaemia the higher was the extraction. The post-ligation rise in oxygen consumption was sustained only in the reactor group, to fall dramatically during hyperoxia. Symbols as in *Fig.* 3.

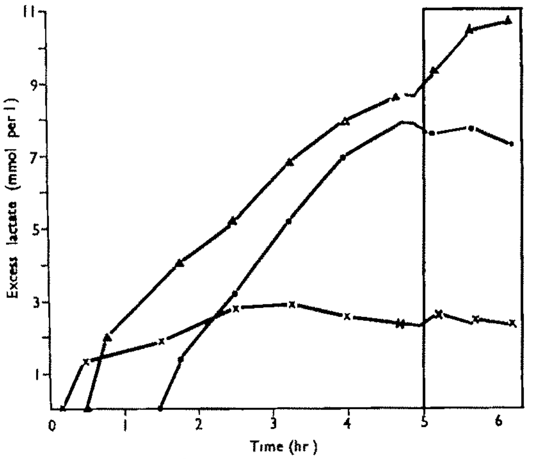

Fig. 6.—Excess lactate in the three groups. Again the non-reactor group differed strikingly from the other two groups Symbols as in *Fig.* 3.

Patti, 1972) has been made on 45 paired samples of blood. The results indicate, over a wide range of oxygen content values, a very close relationship between the two methods ($y=1·017x-0·431$; $r=0·993$).

2. **Temperature Correction.**—The temperature of the ischaemic limb fell progressively with sustained ischaemia. The possibility existed that an error in the calculation of oxygen content might have occurred as a result of the animal's mid-oesophageal temperature being used in the calculation. A systematic examination in 8 dogs, however, indicated that this factor could be excluded as a possible source of error.

3. **Arterial Sampling Site.**—The normal site for arterial sampling was the mid-aorta. Arterial blood reaching the ischaemic limb passed through tortuous collateral channels and it was considered that some loss of oxygen might have occurred between the mid-aorta and the distal collateral arteries as they entered the limb. Using the mid-aortic blood for measurement of arterial oxygen content thus might have given a falsely high value for the arteriovenous oxygen content difference. Blood samples were taken, therefore, from several arterial sites within the ischaemic limb. No consistent difference in oxygen content between these and samples taken from the mid-aorta was discovered.

From these further methodological studies it can be accepted that the changes in oxygen extraction and consumption recorded were accurate and that before the oxygen consumption of an ischaemic limb fell below normal in the process of dying there was a phase of increased metabolic activity. Since there was a simultaneous progressive increase in excess lactate in the venous effluent it must be assumed that some tissues of the limb were undergoing anaerobic metabolism at the same time as other tissues had increased aerobic metabolism. The less severe the ischaemic insult the less obvious were these various effects, as seen in the surviving non-reactor limbs. The measurements of venous carbon dioxide tension and excess lactate were considerably more valuable in distinguishing between different groups of animals than the absolute measurement of blood-flow. The combined effects of the disturbances in the respiratory and non-respiratory components of acid–base balance resulted in a difference in venous *p*H of from 0·13 to 0·38 unit between non-reactor surviving limbs immediately prior to hyperoxia and the other two groups (means of 7·22 and 7·09/6·84 units respectively).

The effect of hyperbaric oxygen administration in experimental limb ischaemia seemed to take three principal courses. In the limbs in which the ischaemic insult was most severe there was little if any effect other than an increase of 15–20 mm. Hg in venous oxygen tension, which can, therefore, be taken to be of little value as an indicator of improved tissue oxygenation. The same general comments may be made of the limbs in which the ischaemic insult was least severe, i.e., the surviving non-reactor limbs, in which the metabolic disturbances were minimal. Blood-flow in the remaining 40 per cent of the animals, i.e., the surviving reactor limbs, was at a critical level since, although the absolute flow reduction was not distinguishable from that of the other surviving limbs, the metabolic changes were comparable to those in the dying limbs. The changes in this group during hyperoxia suggest that some areas ceased to receive any blood supply, which would account for the reduced total effluent blood-flow. The remaining areas, however, would appear to have been better oxygenated, as suggested by the levelling off of the venous carbon dioxide tension and reduction in excess lactate formation.

If these conclusions are correct it would be important in future studies to determine which tissues cease to receive a blood-supply and which are better oxygenated. Thereafter, pharmacological methods of altering the distribution of ischaemic blood-flow could be investigated, as previously described in chronic peripheral ischaemia in patients undergoing hyperbaric oxygenation (Schraibman and Ledingham, 1969b). Of considerable practical interest was the observation that the venous oxygen tension gave no clue as to the variation in tissue oxygen exchange occurring in the different groups of ischaemic limbs. Of much greater value were the measurements of venous carbon dioxide tension, excess lactate, and *p*H.

COMPARISON OF TWO ELECTROLYTE SOLUTIONS FOR SHORT PERFUSION AND HYPOTHERMIC STORAGE IN EXPERIMENTAL RENAL PRESERVATION

BY J. F. GRENIER, J. DAUCHEL, D. JAECK, J. KACHELHOFFER, AND C. STOCK
61ST UNITY OF I N.S R E.M., HOSPICES CIVILS-CHIRURGIE B, STRASBOURG, FRANCE

SUMMARY

In recent years the need for preserving kidneys has become of great importance because of the development of renal transplantation. The most effective and practical method yet described to preserve kidneys outside the body appears to be immersion in a cooled solution combined with initial perfusion. The aim of the present study was to compare two perfusates routinely used in this procedure: Collins solution and Perfudex. A total of 22 kidneys was removed and stored with one of these perfusates and then autotransplanted.

Renal function was monitored by radio-isotope measurements: $^{197}HgCl_2$ uptake and radio-hippuran renography. An assessment of the histological evidence of renal damage was made on preserved kidneys 3 months after transplantation.

As judged by the results of these investigations the most satisfactory preservation of kidneys was obtained with the Collins solution. The use of this perfusate allows a storage time of 24 hours without decreased function or morphological changes in the kidneys. Other investigators have also confirmed the efficacy of the Collins solution and have provided further evidence for its superiority over conventional perfusates for kidney preservation. The current use of the Collins solution, as now recommended by the *France Transplant Association*, makes the future of clinical kidney transplantation more hopeful.

THE recent development of kidney transplantation has stimulated increased investigation into the problem of renal preservation. Kidney storage is required to allow time for tissue typing and for the preparation of the recipient.

Belzer, Ashby, and Dunphy (1967) and Woods (1971) have been able to preserve dog kidneys successfully for 3, 5, and 7 days with continuous perfusion systems. However, such a complex, bulky, and expensive method cannot provide a suitable solution in clinical transplantation and therefore a more practical method is desirable. It is generally agreed that good preservation of kidneys can also be achieved by hypothermic storage only if the organs have been initially perfused with a cooled electrolyte solution. This procedure is uncomplicated and does not require constant monitoring by a technician. Its efficacy seems chiefly to depend on the perfusate composition, but there is no agreement about the solution to be used. In the present report two conventional perfusates are compared: an electrolyte solution (C_3), described by Collins, Bravo-Shugarman, and Terasaki (1969), the ionic composition of which is similar to that of intracellular fluid, and a dextran-containing plasma substitute (Perfudex) routinely used in Scandinavia (Franksson, Collste, Lundgren, Magnusson, and Wehle, 1967; Brunius, Fritjofsson, and Gelin, 1969).

MATERIALS AND METHODS

Twenty-two dog kidneys were preserved for 24 hours with the Collins solution or with Perfudex and were then reimplanted into their hosts. In fact, much longer periods of kidney preservation could have been undertaken with such a method but preservation for 24 hours seems to provide enough time for pre-transplant studies and for preparing the recipients. *Table I* lists the composition of the solutions used in this procedure; solution C_3 was identical to that described by Collins and others (1969) except for the reduction of magnesium sulphate in order to prevent the turbidity which results from its addition. Heparin was added to Perfudex in the same proportions as to C_3.

Table I.—CONSTITUENT OF THE TWO MODIFIED SOLUTIONS USED IN THE PRESENT STUDY

Constituent	*Perfudex*	*Solution C_3*

KH_2PO_4 (g. per l.)	0·06	2·05
$K_2HPO_4.3H_2O$ (g. per l.)	—	9·70
$MgSO_4.7H_2O$ (g. per l.)	0·20	3 69
Glucose or dextrose (g. per l.)	1·00	25·00
Dextran 40 (g. per l.)	0·5	—
Heparin (I.U.)	5 000	5·000
Procaine (g. per l.)	—	1
Papaverine (g. per l.)	—	0 015

Preservation and Autotransplantation Procedures.—The left kidney was removed through a flank incision and immediately perfused for about 5 minutes, with the storage solution cooled to 4° C., from a height of 100 cm. through a catheter introduced into the renal artery. The kidney was then stored for 24 hours before reimplantation.

Group 1: *Collins.*—Eight kidneys flushed with perfusate C_3 were immersed in this solution cooled to 4° C. as described by Collins and others (1969).

Group 2: *Perfudex.*—Nine kidneys perfused with Perfudex were wrapped in a gauze compress moistened in this solution and kept at a temperature of 4° C.

Group 3: *Modified Perfudex.*—Five kidneys which were also perfused with Perfudex were stored by simple immersion in this solution in the manner described for group 1.

Group 4: *Control*.—Two kidneys were immediately reimplanted without preservation.

Reimplantation was carried out through a midline incision. The kidney was revascularized by the anastomoses of the renal vein end to side with the iliac vein and of the renal artery end to end with the external iliac artery. The ureter was anastomosed to the bladder.

Assessment of Renal Function after Transplantation.—Two radio-isotope measurements were used for assessing the transplant's functional status.

Renal $^{197}HgCl_2$ *Uptake*.—Because of the affinity of the mercury atom for tubular cells the injection of $^{197}HgCl_2$ provides a way of studying the kidney's viability by scanning of the renal surface. The renal

scintigram affords an impression of size and form of the kidney and so enables the viability of the renal parenchyma to be affirmed. However, this scan does not give evaluation of renal function. Raynaud, Desgrez, and Kellershohn (1969) showed that a quantitative measurement can be made of such a scintigraph for obtaining information on renal function; this is the measurement of the fixation rate of $^{197}HgCl_2$.

This measurement was performed 1 day before preservation and then 1, 3, 6, and 10 weeks after transplantation. $^{197}HgCl_2$ in a dose of 500 μc. was injected intravenously. The percentages of this dose taken up by the transplanted kidney and by the contralateral kidney were determined after subtracting the background radiation on the third day after mercury injection. Usually 15 ± 5 per cent of the injected $^{197}HgCl_2$ is fixed in each kidney (*Fig.* 1).

Radio-hippuran Renogram.—This test was performed at the same time as $^{197}HgCl_2$ scintigraphy. ^{131}I-labelled ortho-iodohippurate (hippuran) was given as a single intravenous dose of 5 μc. for each study. Radioactivity was determined by placing over each kidney a sodium iodide crystal scintillation probe connected to a ratemeter and a rectilinear recorder. The normal renogram exhibits three segments: the vascular segment, the secretory segment, and the excretory segment. The first is a rapid rise of radioactivity on the tracing which may be ascribed to the radio-hippuran reaching the kidney's vessels. A second phase then occurs in which radioactivity rises more slowly. This is due to differential concentration of the material by the kidney and is assumed to be evidence of active tubular transport of the ortho-iodohippurate (Collins and Richard, 1965). The third segment, in which the radioactivity decreases, relates to the excretion of the secreted radioactive material. In fact, the three phases are not exactly in succession since the process of excretion begins during the second phase.

Following the work of Collins and Richard (1965) and in the belief that any rise in concentration of radioactivity during the second phase was evidence of extraction by functioning proximal tubular epithelium, it has been assumed that the slope of the secretory segment is of value in the study of renal function. This slope is dependent on the concentration of the hippuran reaching the intravascular space in the area 'seen' by the probe. This implies that the measurement of this slope is only reliable in the assessment of renal function if the height of the vascular segment is considered. Therefore, we have defined an index (i) of radio-hippuran uptake which has been determined 80 seconds after the beginning of the test, because at this time the process of secretion is not yet competing with that of excretion.

$$i = tg\,\alpha/v,$$

where $tg\,\alpha$ is the slope of the secretory segment at 80 seconds, and v is the radioactivity detected at the end of the vascular segment.

$$tg\,\alpha = h/t,$$

where h is the increase in radioactivity detected between the end of the vascular segment and 80 seconds, and t is the time of the determination of the index (80 seconds).

$$i = \frac{h/t}{v} = \frac{h/v}{t} = \frac{\text{concentration}}{\text{time}}.$$

Thus, this index must be considered as active concentration per minute. *Fig.* 2 illustrates this.

Histological examination of the transplanted kidneys was performed 3 months after transplantation.

RESULTS

Radio-isotope Measurements.—The measurements recorded 10 weeks after transplantation were compared with those obtained preoperatively. Thus, for each transplanted kidney (T.K.) a rate of functional recovery at the tenth week was calculated from the following formula (*Table II*),

$$R_1 \text{ (per cent)} = \frac{\text{T.K. index of radio-hippuran uptake at 10 weeks}}{\text{T.K. index of radio-hippuran uptake before transplantation}}$$

For each dog the rate of $^{197}HgCl_2$ fixation of the transplanted kidney was compared with that of the contralateral kidney (R.K.) before preservation and at 10 weeks after transplantation (*Table III*).

$$R_2 \text{ (per cent)} = \frac{\text{At 10 weeks (T.K. rate of } ^{197}HgCl_2 \text{ fixation)/(R.K. rate of } ^{197}HgCl_2 \text{ fixation)}}{\text{Before transplantation (T.K. rate of } ^{197}HgCl_2 \text{ fixation)/(R.K. rate of } ^{197}HgCl_2 \text{ fixation)}}$$

Most kidneys (6 out of 8) preserved with the Collins solution showed good recovery of function: $R_1 > 70$ per cent; $R_2 > 70$ per cent. In contrast, of the 14 kidneys perfused with Perfudex, 9 failed to function: $R_1 < 30$ per cent; $R_2 < 30$ per cent. No clear-cut difference was noted between groups 2 and 3; the bad results of these groups appeared to be due to the composition of Perfudex and were not affected by the storage technique of either immersion or wrapping in a compress.

Histological Examination.—The histological changes observed on the transplanted kidneys were graded blindly for comparative purposes as slight (+), moderate (+ +), or severe (+ + +).

Slight changes: These consisted of interstitial oedema and congestion in a few glomeruli. Some of the tubules were lined by regenerating flattened epithelium.

Moderate changes: Extravasation of red blood-cells was noted in the interstitium. The glomerular cells showed hydropic degeneration and large amounts of proteinaceous material were found in the tubules.

Severe changes: Interstitial fibrosis was observed with vacuolation in the glomerular tufts and cellular necrosis in the tubules.

In *Fig.* 3 the transplanted kidneys have been divided into three groups according to this grading. The most severe changes were found in the kidneys preserved with Perfudex, while those perfused by the Collins solution showed minimal changes. Thus the histological examination confirmed the results obtained by radio-isotopic measurement as to the efficacy of solution C$_3$ compared with Perfudex as a perfusate for hypothermic kidney preservation.

DISCUSSION

Renal autotransplantation appears to be the most practical procedure for assessing the efficacy of a preservation technique without adding immunological problems (Dunphy and Jacob, 1960). Although many studies have been done on the important problem of how to recognize kidneys which have suffered damage during preservation all the tests so far described, such as histological examination (Fisher, Copeland, and Fisher, 1967), oxygen consumption determination (Lannon, Tukaram, Olivier, MacKinnon, and Dossetor, 1967), surface *p*H measurements (Alexander, Dmochowski, Murray, and Couch, 1970), and the tetrazolium test (Terazaki, Martin, and Smith, 1967), often do not provide enough information to judge whether a preserved kidney is suitable for transplantation. Moreover, contralateral nephrectomy was not performed in our experimental procedure because it has several disadvantages. Since stored kidneys always demonstrate some degree of reduced function simultaneous removal of the opposite kidney provides too severe a test. By contrast, when contralateral nephrectomy is performed later, the function of the stored kidney cannot be assessed by conventional methods for several weeks. The radio-isotopic measurements used in the present study have enabled us to assess the function of both the transplanted and the remaining kidneys. The correlations observed between these results and the histological examination have been aimed chiefly at establishing the value of the quantitative tests of renal function (*Fig.* 4). Thus in only 2 cases (dogs C$_4$ and C$_{29}$) was there no correlation between the findings.

The value of the radio-isotopic investigations in assessing renal function has been confirmed by numerous reports. Sharpe, King, Hume, Lee, and Kauffman (1966), Burke and Halko (1967), and Magnusson, Collste, Franksson, and Lundgren (1967) showed that ^{131}I hippuran renography has its greatest value when performed serially in the follow-up studies of renal grafts. Raynaud and others (1969) drew attention to the good agreement between measurement of the rate of ^{197}HgCl$_2$ fixation and other renal-function tests, especially creatinine and PAH clearance. This measurement was also thought by Cendron, Raynaud, and Desgrez (1970) to be extremely valuable for making separate records of the renal function in dogs in view of the multiple sources of error in separate catheterization.

Our observations are similar to the results obtained by other groups working in this field. Collste, Bjorken, Collste, and Groth (1970) and Collins, Hartley, and Clunie (1971) conducted experimental series of kidney preservation in which direct comparison was made between the C$_3$ solution and a dextran-containing plasma substitute, and they confirmed the greater efficacy of the C$_3$ solution. Successful renal preservation for 48 hours has been obtained by these authors and by Wen Pen Liu, Humphries, Russel, Stoddard, and Moretz (1971) after brief perfusion and hypothermic storage using the Collins solution. On the other hand, Brunius and others (1969), who obtained the best results with

Perfudex, did not report successful kidney preservation in excess of 24 hours.

The reasons for the more beneficial effects of intracellular electrolyte solutions are well known because of the present knowledge of tissue injury occurring during hypothermic storage. When used for long periods of preservation cooling can induce severe renal damage.

Vascular Thrombosis.—This results from the activation of cold agglutinins (Lofstrom and Zederfeldt, 1967) and from the increase in the blood viscosity (Levy, 1959). In fact, the development of flow obstructions can be avoided by brief perfusion before storage (Cleveland, Lee, Prout, and Hume, 1964). Perfudex, which contains low molecular weight dextran 40, seems to give rise to an effective wash-out of red cells because of its viscosity-lowering and non-aggregating effect (Hitchcock, Kiser, Telander, and Peterson, 1964). The efficiency of dextran 40 in clearing the kidney of formed blood elements has been demonstrated by Kerstein, Bergentz, and Lewis (1970). The Collins solution in addition to its similarity to intra-cellular ionic composition also has some ability to effect a wash-out of the capillary bed: the lack of a sodium–potassium gradient because of the presence of C_3 in the capillary lumen causes the membrane potential of the vascular smooth muscle to be low. The resulting passive vasodilatation would improve the wash-out of red cells (Langer, 1968). However, it would appear that C_3 is significantly less effective in clearing the kidney than Perfudex, but this effect is obviously not essential prior to renal preservation.

Cellular Ionic Disturbances.—Hypothermia lowers the renal metabolic rate so that the energy requirements are less than normal. It also reduces the active membrane transport mechanisms. Therefore the renal cells gain water and sodium and lose magnesium and potassium when the kidney is stored in the cold (Ennerson, 1966; Keeler, Swinney, Taylor, and Uldall, 1966). These ionic shifts resulting from diffusion down concentration gradients cause cellular damage. There is evidence that preservation of cellular architecture can only be ensured by perfusates close to intracellular ionic composition which are able to reduce the entry of sodium into the cell and the loss of potassium. Wallach, Cahill, Rogan, and Jones (1962) and Kamiyama, Webb, and Ecker (1970) have speculated on the mechanism of the protection offered by the high concentration of magnesium in the Collins solution. They contended that it was due to a 'stabilizing' effect on the lysosomal membrane. Indeed, during preservation kidneys always suffer some degree of ischaemia, which if severe can cause lysosomal membrane rupture, release of acid hydrolases, and intracellular digestion (Groenwald, Weber, Van der Walt, Greeff, and Van Zyl, 1971). Finally, the hyperosmolarity of the Collins solution reduces cellular swelling. This also is a factor of importance.

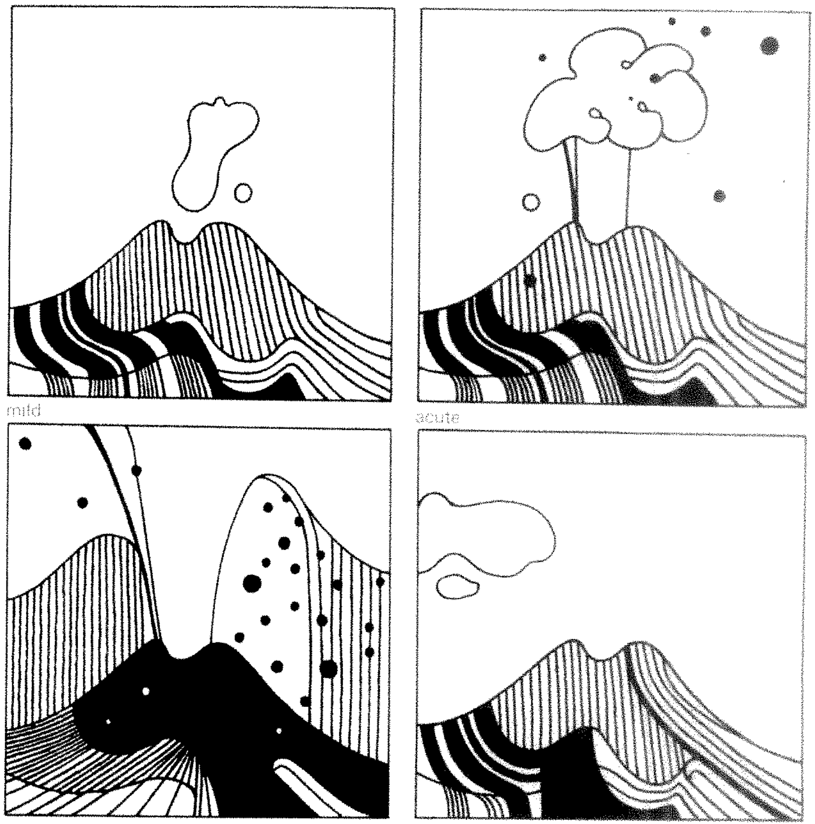
For all stages of Ulcerative Colitis



"Fortunately, Sulphasalazine tablets, 0.5 grams. 4 times a day will prevent relapses in the majority of patients with colitis, and only a few patients cannot tolerate this relatively small dose, which can be continued indefinitely, since we do not know when, if ever, it can be safely stopped."

General Practitioner, April 7 (1972).

In the treatment of the acute attack, sulphasalazine may produce rapid, dramatic improvement in the patient's condition. A similar specific action of sulphasalazine is seen in late post-dysenteric colitis in patients in whom steroid therapy has failed."

Lancet (1973), I, 698

Salazopyrin (sulphasalazine) is available as the plain 0.5g. tablet, 0.5g. EN-tab and as an 0.5g. suppository.

Literature and detailed information on Salazopyrin are available on request.

REGENERATION OF PARIETAL AND VISCERAL PERITONEUM IN THE IMMATURE ANIMAL: A LIGHT AND ELECTRON MICROSCOPICAL STUDY

By A. T. Raftery

Department of Anatomy, School of Medicine, University of Leeds

Summary

1. The healing of visceral and parietal peritoneum has been investigated in the immature animal by both light and electron microscopy.

2. Healing has been found to occur more rapidly in the immature animal when compared with the adult animal. Parietal peritoneum was covered by a new mesothelium in 7 days, while the liver was covered in 5 days.

3. The new mesothelium developed from subperitoneal perivascular connective-tissue cells but it was not possible to determine whether these were primitive mesenchymal cells or fibroblasts.

4. The findings are discussed in relation to the pathogenesis of peritoneal adhesions.

The healing of peritoneum in the immature animal is of interest in view of the fact that intestinal obstruction due to peritoneal adhesions is more common following abdominal surgery in early life (Devens, 1963; Replogle, Johnson, and Gross, 1966), especially in the neonatal period. The greater incidence and severity of adhesions in the infant compared with the adult may reflect a difference in the nature of healing of peritoneum. Ellis, Harrison, and Hugh (1965) have shown that peritoneal regeneration occurred more rapidly in the immature rat than in mature ones, but flattening of the surface layer of cells, as seen in paraffin sections cut perpendicular to the wound surface, was used as a criterion for assessing complete mesothelial regeneration. This has been shown to be an inadequate method of assessment and the need for Häutchen preparations in which the surface cells are viewed *en face* has been stressed (Eskeland, 1966; Raftery, 1973a). The present investigation was undertaken to determine, by both light and electron microscopy, the nature of peritoneal regeneration in the immature animal and to compare the findings with those for the adult animal (Raftery, 1973a, c).

MATERIALS AND METHODS

A total of 92 male Sprague-Dawley rats weighing 50–60 g. was used in this investigation. The rats were anaesthetized with ether and the abdominal cavity was opened through a midline incision 3 cm. long. The operative technique was clean but not strictly aseptic. Wounds approximately 1 mm. deep and either 0·5 × 0·5 cm. or 1 × 1 cm. were made in the liver capsule by a tangential cut with a scalpel blade. A wound was also made on each side of the midline in the parietal peritoneum, that on the left side being 2 × 2 cm. and that on the right side 1 × 1 cm. The peritoneum, together with the underlying layer of muscle, was removed within this area. The abdominal incision was closed in two layers, catgut sutures being placed through the musculoperitoneal layer and silk sutures through the skin. Animals were killed by exsanguination under ether anaesthesia at 12 hours, 24 hours, and at daily intervals up to 8 days after operation. At least 3 animals were examined at each stage.

The liver was removed, rinsed briefly in 5 per cent glucose, immersed in 0·25 per cent silver nitrate for 30 seconds, rinsed again in 5 per cent glucose, and then fixed in 10 per cent formol–saline for 8–12 hours. The wounds in the parietal peritoneum were removed together with a wide margin of adjacent peritoneum, pinned flat on cork, and treated in the same manner as the liver. Häutchen preparations of the wounds were subsequently made as described by Eskeland (1966) and stained with haematoxylin. In other animals the wounds were excised, fixed in formol–sublimate or Bouin's fluid, dehydrated, and embedded in paraffin wax. Serial sections were cut perpendicular to the wound surface at 6 µm. These sections were stained with haematoxylin and eosin and by either the picro-Gomori method or Ledrum's stain (Humason, 1962) for fibrin and collagen.

Specimens of parietal peritoneum and liver were also fixed in 2·5 per cent glutaraldehyde in 0·1 *M* cacodylate buffer, post-fixed in 1 per cent osmium tetroxide in 0·1 *M* phosphate buffer, dehydrated in graded solutions of ethanol, passed through epoxypropane, and embedded in Araldite. Sections 1 µm. thick were cut on an LKB Ultrotome III, stained with methylene blue–Azure II (Richardson, Jarett, and Finke, 1960), and examined by light microscopy. Such sections were cut from specimens obtained from different areas of the wound surface. When appropriate areas were found, thin sections were cut, mounted on uncoated grids, and either stained with lead citrate alone (Reynolds, 1963) or double stained with uranyl acetate (Stempack and Ward, 1964) and lead citrate, prior to examination in an AEI type EM6B electron microscope.

In order to label the peritoneal macrophages some animals were given an intraperitoneal injection of 1 ml. of a 0·2 per cent suspension of polystyrene spheres (0·79 µm. diameter Dow–Latex; Serva, Feinbiochemica, Heidelberg) in 0·9 per cent saline at the time of operation. Specimens from these animals were processed for Häutchen preparations in order to check if the inflammatory reaction caused by the polystyrene spheres had any effect on the nature of healing. Some specimens were processed for electron microscopy as described above. Some normal animals were given an intraperitoneal injection of 1 ml. of a 0·2 per cent suspension of polystyrene spheres in order to check that normal mesothelial cells and subperitoneal fibroblasts did not ingest polystyrene spheres. Specimens of parietal and visceral peritoneum from these animals were fixed in 2·5 per cent glutaraldehyde, processed as described above, and examined by electron microscopy.

RESULTS

1. Macroscopic.—Adhesions to the wounds were found in 16 animals and in all but one of these the liver was adherent to part of the wound in the parietal peritoneum. The one exception was an adhesion between the omentum and parietal peritoneum.

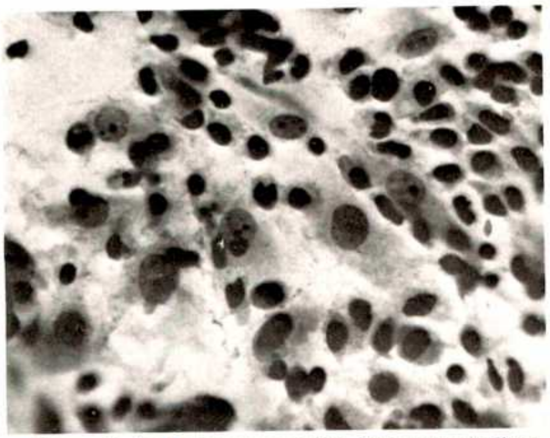

FIG. 1.—Parietal peritoneum at 2 days. Two types of cell are seen on the wound surface: one resembling a monocyte, the other a large cell with an indistinct boundary, prominent nucleoli, and pronounced cytoplasmic basophilia resembling a fibroblast. Häutchen. (× 450.)

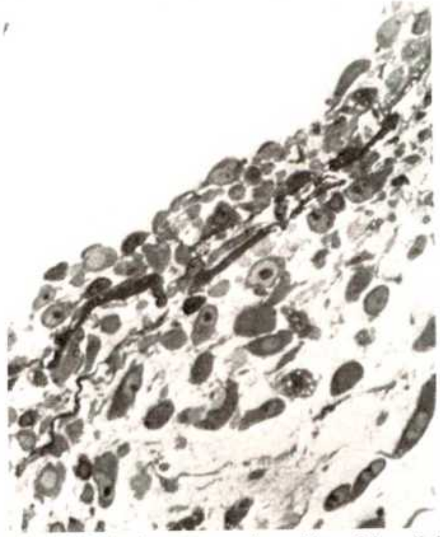

FIG. 2.—Parietal peritoneum at 2 days. Most of the cells in the deeper parts of the wound resemble fibroblasts. Similar cells are also seen in the more superficial parts of the wound. 1 μm. Araldite section, methylene blue–Azure II (MB–AII). (× 220.)

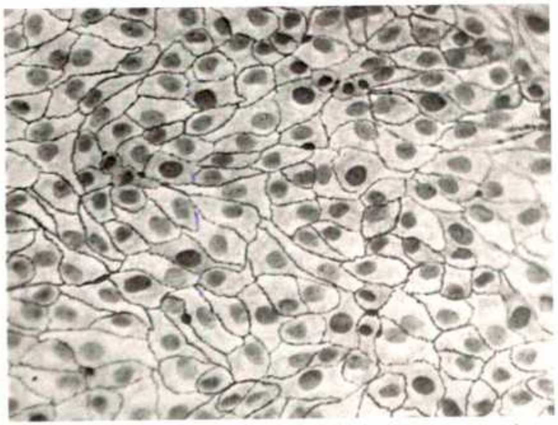

FIG. 3.—Parietal peritoneum at 7 days. Note the complete healing of the mesothelial layer; occasional mitotic figures are seen on the wound surface. Häutchen. (× 280.)

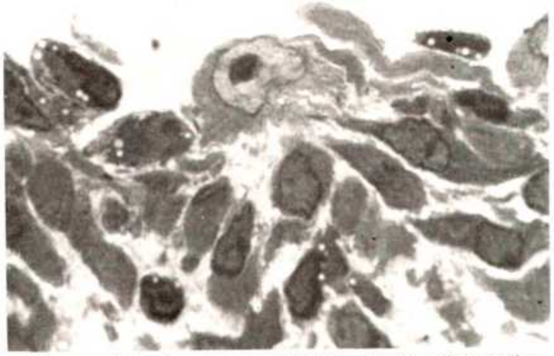

FIG. 4.—Parietal peritoneum at 4 days. A large cell possessing a prominent nucleolus and resembling a fibroblast is seen on the wound surface. Note that, in contrast to the macrophages, it contains no polystyrene spheres. 1 μm. Araldite section, MB–AII. (× 900.)

During the first 24 hours the wounds were uneven and haemorrhagic, but by 2 days they were paler, and by 3 days they were usually smooth and glistening. At 5 days it was difficult to distinguish the wound from the normal surrounding parietal peritoneum. The wounds in the liver capsule appeared as greyish-white puckered areas and were easily visible at 8 days.

2. Light Microscopy.—

Control Animals.—Following intraperitoneal injection of polystyrene spheres into normal animals none was seen in mesothelial cells or subperitoneal fibroblasts.

Intraperitoneal injection of polystyrene spheres did not have any discernible effect on the time or nature of peritoneal healing.

a. Parietal Peritoneum.—The cellular changes which occurred on the wound surface, in its base, and in the adjacent peritoneum were similar to those reported for the adult animal (Raftery, 1973a) but occurred more rapidly in the immature animal. Thus, by 2 days after operation the initial acute inflammatory response had subsided and two well-defined types of cell were seen on the wound surface (*Fig.* 1): one was a small round cell with a dark staining, eccentric, kidney-shaped nucleus which was identified as a cell of the monocyte/macrophage type, and the other was a large cell with an ill-defined boundary, having a large, round, or oval nucleus, containing one or more prominent nucleoli and with pronounced cytoplasmic basophilia. The latter resembled fibroblasts. The above changes were not seen until 3 days in the adult animal. In sections cut perpendicular to the wound surface marked fibroblastic proliferation was seen in the base of the wound at 2 days (*Fig.* 2), and only occasional macrophages were seen. The number of monocyte-like cells on the wound surface gradually decreased and at 5 days only the fibroblast-like cells remained. These cells came into contact with one another as shown by complete silver lines in Häutchen preparations, and reconstituted the new mesothelium. Healing was completed by 7 days (*Fig.* 3) compared with 8 days in the adult animal.

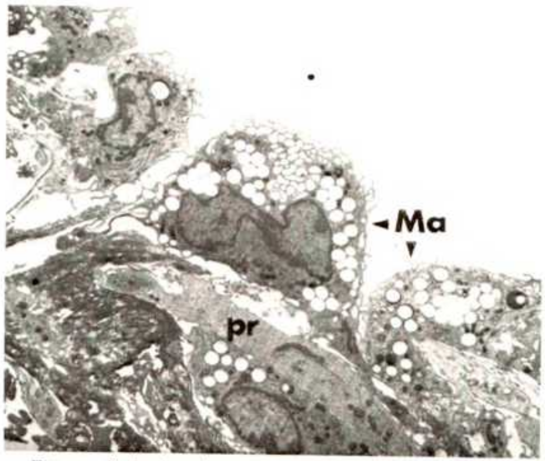

FIG. 5.—Parietal peritoneum at 2 days. Macrophages (**Ma**) containing polystyrene spheres rest on a fibrin base. A process (**pr**) of a primitive mesenchymal cell extends towards the wound surface. Uranyl acetate (UA) + lead citrate (LC). (× 2000.)

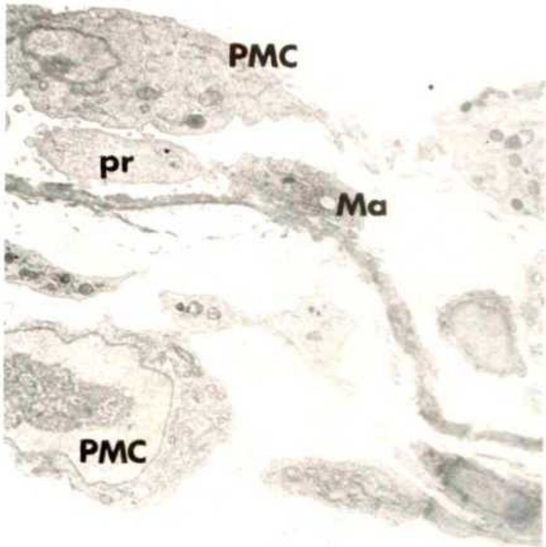

FIG. 6.—Parietal peritoneum at 2 days. Primitive mesenchymal cells (**PMC**) are seen on the wound surface and in the base of the wound. A process (**pr**) of a primitive mesenchymal cell and part of a macrophage (**Ma**) containing a polystyrene sphere are also seen. LC. (× 3000.)

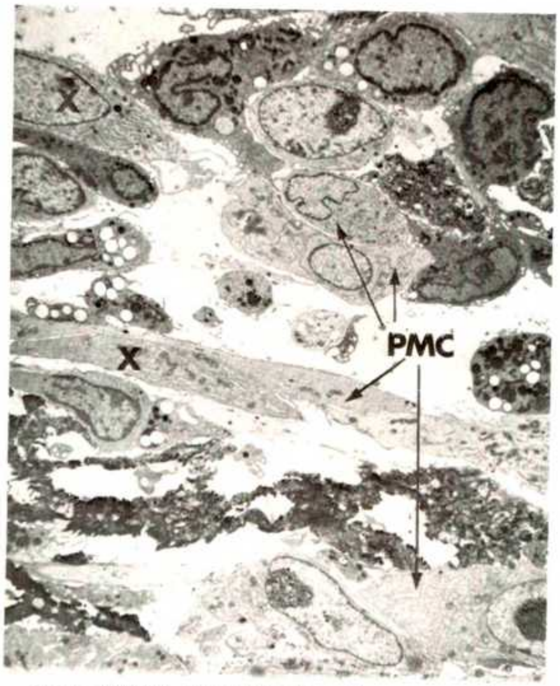

FIG. 7.—Parietal peritoneum at 2 days. Numerous macrophages and primitive mesenchymal cells (**PMC**) are seen in the base of the wound. Some cells (**X**) have some characteristics common to both primitive mesenchymal cells and fibroblasts and probably represent intermediate forms between the two. Polystyrene spheres are seen only in macrophages. UA + LC. (× 2000.)

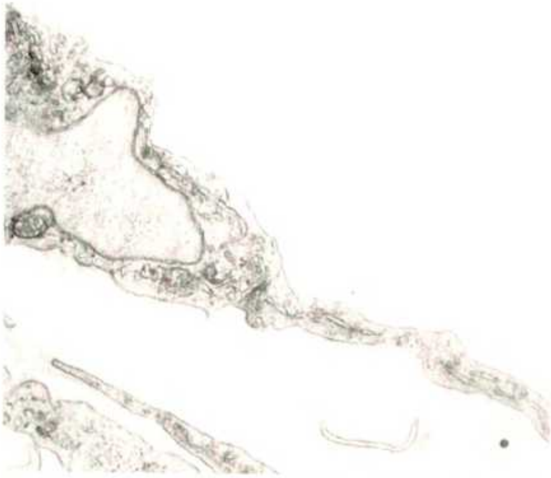

FIG. 8.—Parietal peritoneum at 2 days. A long process of a primitive mesenchymal cell extends along the wound surface. LC. (× 7500.)

Throughout the course of healing polystyrene spheres were seen only in cells of the monocyte/macrophage type (*Fig.* 4) and never in fibroblasts or mesothelial cells. There was no difference in the time or nature of healing between small and large wounds.

b. Liver.—Healing of wounds in the liver capsule closely resembled the healing of parietal peritoneum for the most part. Again healing of the wound occurred more rapidly than in the adult animal and a complete layer of mesothelium had covered the wound by 5 days compared with 7 days in the adult animal. There was no difference in the time or nature of healing between small and large wounds.

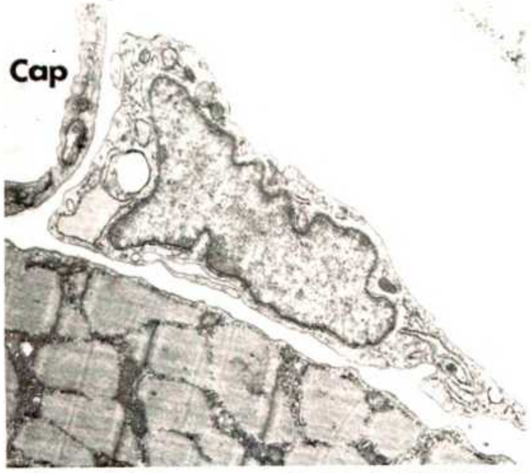

FIG. 9.—Parietal peritoneum at 2 days. A perivascular connective-tissue cell is seen adjacent to a capillary (**Cap**). This cell closely resembles a primitive mesenchymal cell. LC. (× 7500.)

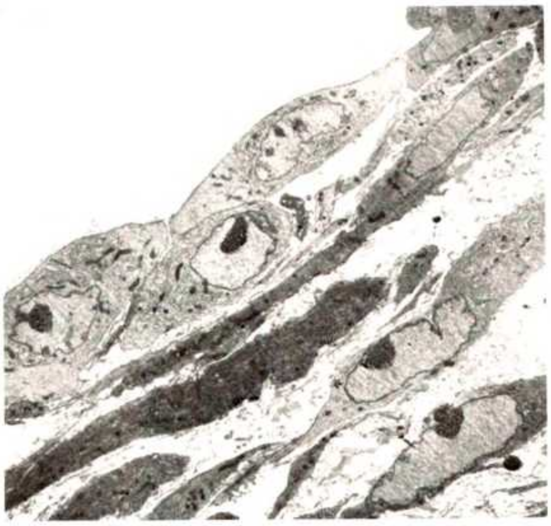

FIG. 11.—Parietal peritoneum at 5 days. The surface cells closely resemble the underlying fibroblasts in nuclear and cytoplasmic characteristics. UA + LC. (× 2750.)

3. Electron Microscopy.—The findings for parietal peritoneum and liver will be described together and where any variation occurred this will be pointed out at the relevant stage.

12 *Hours*.—Numerous cells were seen entangled within fibrin strands. Polymorphs predominated but macrophages and a few eosinophils and mast cells were also seen. Polystyrene spheres were seen in polymorphs and macrophages. No detached mesothelial cells were seen on the wound surface.

24 *Hours*.—The majority of cells on the wound surface were macrophages resting on a fibrin base. No cells which could be identified as detached mesothelial cells were seen on the wound surface.

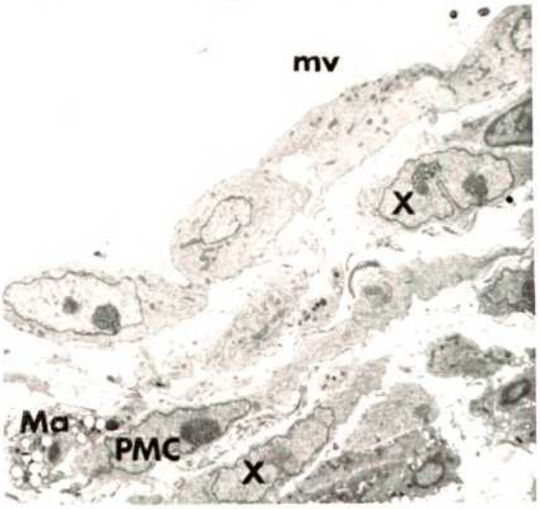

FIG. 10.—Parietal peritoneum at 3 days. The surface cells possess microvilli (**mv**) and have nuclear and several cytoplasmic characteristics in common with primitive mesenchymal cells (**PMC**) and proliferating fibroblasts. Some cells (**X**) appear intermediate in form between primitive mesenchymal cells and proliferating fibroblasts. Note that polystyrene spheres are seen only in macrophages (**Ma**). LC. (× 1750.)

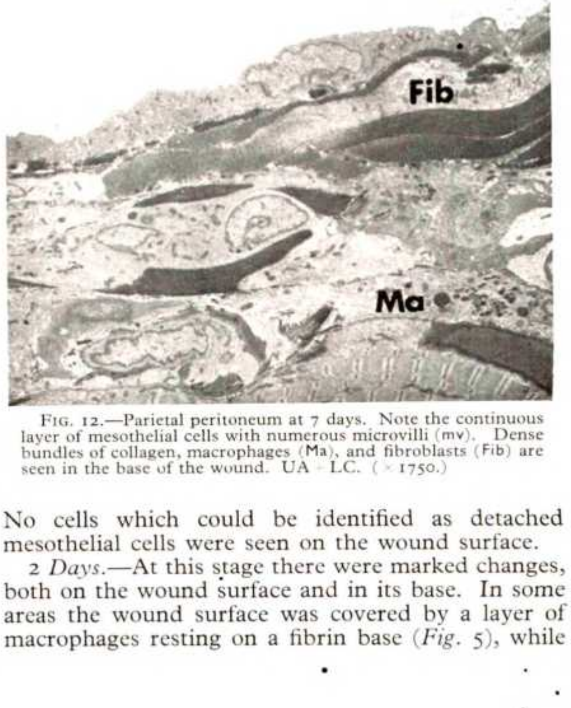

FIG. 12.—Parietal peritoneum at 7 days. Note the continuous layer of mesothelial cells with numerous microvilli (**mv**). Dense bundles of collagen, macrophages (**Ma**), and fibroblasts (**Fib**) are seen in the base of the wound. UA + LC. (× 1750.)

2 *Days*.—At this stage there were marked changes, both on the wound surface and in its base. In some areas the wound surface was covered by a layer of macrophages resting on a fibrin base (*Fig.* 5), while

in others, primitive mesenchymal cells were seen (*Fig.* 6). Even in areas where macrophages predominated on the wound surface, numerous primitive mesenchymal cells were seen in the base of the wound (*Fig.* 7). Many of the latter possessed long processes which extended towards the wound surface (*Fig.* 5). These processes contained chiefly aggregates of ribosomes and few other organelles. In areas where primitive mesenchymal cells were present on the wound surface long processes often extended from them along the wound surface (*Fig.* 8). There was a close similarity in nuclear and cytoplasmic characteristics between primitive mesenchymal cells on the wound surface (*Fig.* 8) and perivascular connective-tissue cells in the base of the wound (*Fig.* 9). No detached mesothelial cells could be identified on the wound surface at this stage. Polystyrene spheres were seen only in macrophages and never in primitive mesenchymal cells.

3 *Days* (*Fig.* 10).—At this stage very few macrophages remained on the wound surface. The majority of cells seen on the wound surface resembled the proliferating fibroblasts or primitive mesenchymal cells in the base of the wound in nuclear and cytoplasmic characteristics except that adjacent cells were often joined by tight junctions. In many cases it was not possible to draw a sharp distinction between primitive mesenchymal cells and fibroblasts and many cells appeared intermediate in form between the two. Small amounts of collagen were now seen in the base of the wound. Macrophages were the only cells to contain polystyrene spheres.

4 *Days.*—The appearances were similar to those at 3 days.

5 *Days.*—At this stage there were differences between the wounds in the parietal peritoneum and the liver. The cells on the surface of the wounds in the parietal peritoneum were of uniform appearance and, apart from microvilli and tight junctions, closely resembled proliferating fibroblasts in the base of the wound in both nuclear and cytoplasmic characteristics (*Fig.* 11). However, tight junctions were not always seen between cells on the wound surface. In the case of the liver there was a continuous layer of mesothelial cells on the wound surface and either tight junctions or desmosomes were seen between adjacent cells. A basement membrane was seen beneath some mesothelial cells covering the liver at this stage but frequent breaks were observed in it. No basement membrane was observed beneath mesothelial cells covering the wound in the parietal peritoneum.

6 *Days.*—The appearances at 6 days did not differ from those at 5 days in the case of both the liver and the parietal peritoneum.

7 *Days* (*Fig.* 12).—A continuous layer of mesothelial cells was seen on the surface of both the liver and the parietal peritoneum. A basement membrane was seen beneath the mesothelial cells in most areas but gaps in it were still visible. Dense bundles of collagen were seen in the base of the wound together with fibroblasts and macrophages. No polystyrene spheres were seen in mesothelial cells although some were still present in macrophages.

8 *Days.*—The appearances were similar to those at 7 days except that a continuous basement membrane was now seen beneath the mesothelial cells.

DISCUSSION

This study of peritoneal wound healing in the immature animal has in part confirmed the findings of Ellis and others (1965) that peritoneal healing is more rapid in the immature animal. The earlier authors noted a flattened layer of cells on the wound surface at 3 days as well as numerous elongated fibroblasts in the base of the wound. The present study has shown that, while cells on the surface of the wound in the parietal peritoneum were mainly flattened by 3 days, complete mesothelial regeneration did not occur until 7 days, as shown by Häutchen preparations, compared with 8 days in the adult animal. In the case of the visceral peritoneum covering the liver healing was complete by 5 days, compared with 7 days in the adult animal (Raftery, 1973a).

Previous investigations have led to the conclusions that the new mesothelium arises by three possible mechanisms:—

1. Transformation of peritoneal macrophages.
2. Metaplasia of subperitoneal connective-tissue cells.
3. Seeding of mesothelial cells from the adjacent normal peritoneum.

It has been shown (Raftery, 1973a, c) that there is no evidence to support the theory that seeding of mesothelial cells from adjacent surfaces makes a significant contribution to peritoneal healing, although a few mesothelial cells are present in the peritoneal fluid of operated animals (Raftery, 1973b). Also no evidence was found to support the theory that peritoneal macrophages are transformed into mesothelial cells either directly or via fibroblasts. It was concluded that the new mesothelium arose from subperitoneal perivascular connective-tissue cells but it was not possible to determine whether these were primitive mesenchymal cells or fibroblasts (Raftery, 1973c). Undifferentiated primitive mesenchymal cells are considered to be present in the perivascular connective tissue and to have the potentiality of becoming transformed into other types of cells (Maximow, 1927).

The ultrastructural study of peritoneal regeneration in the immature animal did not provide any evidence to support the theory that macrophages were transformed into fibroblasts or mesothelial cells. If the latter were true it is likely that at some stage polystyrene spheres would be seen in fibroblasts and mesothelial cells. At a time when macrophages were filled with polystyrene spheres none was seen in fibroblasts or mesothelial cells. It is concluded that in the immature animal, as in the adult animal, mesothelial cells do not arise by transformation of peritoneal macrophages. No detached mesothelial cells were seen on the wound surface in the early stages of healing and it is therefore concluded that the new mesothelium does not arise by seeding of mesothelial cells from the adjacent peritoneum. The results of the light microscopical study suggested that the new mesothelium arose by metaplasia of subperitoneal fibroblasts. However, correlation of the results obtained by light and electron microscopy indicated that many of the cells which were designated as fibroblasts on the basis of light microscopy represented a spectrum of cells ranging from primitive mesenchymal cells to mature fibroblasts. The results suggest that the new mesothelium arises in the immature animal in the same manner as it does in the adult animal, namely from the subperitoneal perivascular connective-tissue cells, but it has not been possible to determine whether these are primitive mesenchymal cells or fibroblasts. Proliferation of primitive mesenchymal cells and the appearance of fibroblasts and collagen occur more rapidly in the immature animal. It is suggested that because proliferation of primitive mesenchymal cells and the appearance of fibroblasts occur more rapidly mesothelial regeneration is correspondingly more rapid.

The healing of the visceral peritoneum covering the liver is faster than the healing of the peritoneum of the abdominal wall. This finding is similar to that in the adult animal. The most likely explanation for this finding is that the liver provides a fairly firm substrate for healing while the peritoneum of the anterior abdominal wall is subject to distension.

Adhesions occurred more commonly in the immature animal than in the adult animal. Thus, while in adult animals adhesions were seen in only 6 out of 100 animals and involved adhesion between the liver and the midline laparotomy wound (Raftery, 1973a), in the immature ones adhesions occurred in 16 out of 92 animals and involved adherence between the liver wound and part of the wound in the parietal peritoneum. It has been reported (Howes and Harvey, 1932) that fibroplasia occurs earlier in the immature animal, and in the present study a more rapid proliferation of fibroblasts and appearance of collagen have been observed compared with the adult animal. This may have a bearing on the greater incidence of adhesions in the immature animal. The wounds made in the immature animal were the same size as those made in the adult animal (Raftery, 1973a) and it is possible that the relatively large size of the wound in the immature animals resulted in ischaemia in the base of the wound and adhesions arose as the result of ischaemia, as suggested by Ellis (1962).

How can the concept of mesothelial regeneration from subperitoneal perivascular connective-tissue cells be related to the pathogenesis of peritoneal adhesions? Ellis (1971) stated in his review of the causes of peritoneal adhesions that it has been accepted in the past that absorption of a fibrinous exudate depended on the presence of an intact mesothelium. If this remained intact, it was argued, fibrin disappeared. If it was destroyed persistent fibrous adhesions would develop. It has been shown (Robbins, Brunschwig, and Foote, 1949; Trimpi and Bacon, 1952; Williams, 1955; Ellis, 1962), however, that large peritoneal defects would heal without adhesion formation in the majority of cases, but when an attempt was made to appose the edges of the wounds by sutures, adhesions were formed to the wound (Thomas and Rhoads, 1950; Ellis, 1962; Hubbard, Khan, Carag, Albites, and Hricko, 1967). On the basis of his studies Ellis (1962) concluded that it was not the peritoneal defect itself that was a stimulus to adhesion formation but the presence of ischaemic tissue which probably resulted from pulling the wound edges together under tension with sutures. Hartwell (1955) wrote:—

> 'the characteristics of serosal cells being what they are, it is only logical to believe that they prevent adhesions by combining their fibrinolytic power with their epithelial-like function of extending themselves as a solid sheet of cells to cover any raw surface. This gives them the ability to come between any two apposed musculo-fibrous surfaces which are stuck together only by fibrin, which has not been organised by the growth of granulation tissue or laying down of collagen. Adhesions are composed of collagen fibres. If fibroplasia occurs between two surfaces before motion or before serosal cells grow in to separate them a permanent adhesion will be formed. If serosal covering of one or both of the apposed denuded surfaces be rapid and permanent no adhesions will form.'

At the time that this statement was written there was no evidence to support the claim that serosal cells had fibrinolytic power, but recently Myhre-Jensen, Larsen, and Astrup (1969) have demonstrated fibrinolytic activity in peritoneal mesothelium. Also, the statement regarding the epithelial-like function of serosal cells in extending themselves as a solid sheet to cover any raw surface is erroneous (Ellis and others, 1965; Eskeland, 1966; Raftery, 1973a). Ellis (1962) attributed adhesion formation to ischaemia but does not appear to have considered closely the effect of ischaemia on the mesothelial cells. They would probably undergo necrosis, but firm evidence on this point is lacking. A possible relationship exists between the theory of Ellis and the findings of the present investigation showing that mesothelial cells arise from perivascular cells, be they mesenchymal cells or fibroblasts. Ischaemia could result from either inadequate proliferation of vessels in the base of the wound or, if adequate proliferation of vessels did occur, an inadequate blood-flow in these vessels. In either case it is conceivable that the perivascular connective-tissue cells may not proliferate owing to ischaemia, and mesothelial cells would not appear, or appear more slowly, in the area of ischaemia. The absence of definitive mesothelial cells, with associated fibrinolytic activity, could lead to adhesion formation due to fibroplasia before definitive mesothelial cells grow between the two apposed surfaces. While this is largely conjectural it would suggest that an investigation of the fibrinolytic activity of regenerating mesothelium is required.

The present study has shown that regeneration of peritoneum occurs more rapidly in the immature animal. It has shown also that the new mesothelium arises from subperitoneal connective-tissue cells, but it has not been possible to determine whether these are primitive mesenchymal cells or fibroblasts.

Acknowledgements.—I wish to thank Professor R. L. Holmes for his helpful criticism, Messrs. R. K. Adkin and R. H. Nettleton for technical assistance, Mr. P. McPhie for preparation of the specimens for electron microscopy, and Mrs. Sandra Brougham for typing the manuscript.

PINWORM INFESTATION OF THE APPENDIX

BY P. B. BOULOS* AND A. G. A. COWIE
UNIVERSITY COLLEGE HOSPITAL, LONDON

SUMMARY

Eight cases of pinworm infestation of the appendix presenting with symptoms simulating acute appendicitis are reported from a study of 293 appendicectomy operations performed at University College Hospital, London, in the past 2 years.

In each case a diagnosis of appendicitis was made on clinical grounds but in 6 patients the appendix was normal histologically.

Symptoms mimicking appendicitis but caused by *Enterobius vermicularis* infestation merit recognition as a disease process and treatment to eradicate the worm must not be overlooked.

THE vermiform appendix is an anatomical blind loop of the gastro-intestinal tract within which it is possible for pathogenic organisms to become established, later to manifest their presence in disease. Among the pathogens which may behave in this way are schistosome ova (Turner, 1909; Abdel Shafi, 1940; Elwi and El Tiraei, 1955), *Entamoeba histolytica* (Manson-Bahr, 1946), and *Enterobius vermicularis* (Duran-Jorda, 1957; Coutelen, Deblock, Biguet, and Capron, 1958; Richmond and Guthrie, 1964).

Eggs transferred from an infected patient on the fingers or on towels and linen are ingested and hatch in the gastro-intestinal tract. Mature pinworms inhabit the caecum and appendix and the male worms perish in the bowel. Gravid females, however, migrate to the anus and appear on the perianal skin. where they die liberating their eggs. This process, especially at night, causes intolerable itching and inevitably in time contamination of fingers and fomites. Usually infestation of one member of a family will result in the infestation of the remainder.

Appendicitis caused by obstruction of the appendix by a bolus of worms is recognized, but symptoms simulating appendicitis in the absence of obstruction or secondary infection have not often been reported.

MATERIALS AND METHODS

Surgical specimens removed at operation for appendicitis performed either as an emergency procedure or electively after a mass had settled were studied. Appendices removed in the course of other surgical procedures were excluded. The specimens were fixed by immersion in formol–saline and set in paraffin wax. Microtome sections were cut and stained with haematoxylin and eosin. In the 2 years of this study 293 appendicectomies were performed.

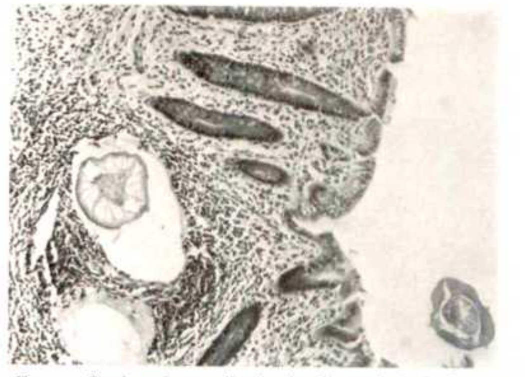

FIG. 1.—Section of appendix showing *E. vermicularis* pinworms in the lumen and embedded in the mucosa, without evidence of active inflammation. (× 138.)

RESULTS

Two hundred and seventeen specimens showed the histological changes of acute bacterial inflammation, 68 specimens were normal, and 8 specimens contained pinworms. Six of the 8 specimens containing pinworms showed no evidence of inflammation despite the presence of the worms and the preoperative clinical picture of appendicitis. Even if the worms lie within the mucosa there may be no active inflammation (*Fig.* 1). *Table I* summarizes the findings in the patients in whom worms were found in the appendix.

DISCUSSION

Symptoms which closely mimic those of appendicitis may be found in association with pinworm infestation (Gross, 1953). Nausea and vomiting, abdominal pain, and tenderness in the right iliac fossa may cause the clinician to decide that appendicectomy is the proper course of action and in a proportion of such patients the appendix will contain pinworms.

---

* Present address: Department of Surgery, Faculty of Medicine, Khartoum, Sudan.

The incidence of infestation is thought to vary according to the environment and to the prevailing standards of hygiene. Figures as high as 57·5 per cent have been reported for children in northern France (Coutelen and others, 1958), and 10·8 per cent for patients in Egypt (Soliman, 1966). In this country specimens from Manchester Children's Hospital showed infestation in 52 of 691 patients, giving an incidence of 7·1 per cent (Duran-Jorda, 1957). In our study we have found an incidence of 2·7 per cent, and it is of interest to note that only in the 2 cases where the patient was over 21 years of age was there evidence of acute inflammation. Usually the worms live in the appendix without causing damage, but eventually they may erode through the mucosa as in the present *Case* 5. Bacterial contamination could arise via this route and it is possible that prolonged infestation is related to the development of inflammatory change.

Table I.—SUMMARY OF THE FINDINGS IN THE PRESENT SERIES

CASE	AGE (yr.)	CLINICAL PRESENTATION	OPERATIVE FINDINGS	HISTOLOGY
1	6	Colicky abdominal pain for 3 days which had localized in the lower abdomen. Anorexia but no vomiting. Temp., 37·7° C. Tenderness and guarding in the right iliac fossa	Normal appendix	Pinworm in the lumen, but no inflammatory changes in the wall
2	7	Central abdominal pain for 2 days which had shifted to the right iliac fossa. She had not vomited, but was generally feeling unwell. Temp., 38° C. Tenderness in the right iliac fossa with gaurding and slight rebound tenderness	Normal appendix	Mild inflammatory changes of the mucosal layer and large lymphoid follicles with hyperplastic germinal centres in the submucosal layer. The appendicular lumen contained adult pinworm
3	12	24-hour history of right iliac fossa pain associated with nausea and vomiting. Temp., 37° C. Tenderness in the right iliac fossa but no guarding or rebound tenderness	Normal appendix	Essentially a normal appendix containing a worm
4	12	4-hour history of pain in the right iliac fossa, anorexia, and nausea. Temp., 38·3° C. Tenderness and guarding in the right iliac fossa	Normal appendix	Segments of pinworms in the lumen with a focal granulamatous eosinophilic reaction at one point in the mucosa
5	17	48-hour history of central colicky abdominal pain which shifted into the right iliac fossa associated with vomiting but no diarrhoea or urinary symptoms. Temp., 37·1° C. Tenderness in the right iliac fossa but no guarding or rigidity	Normal appendix	Atrophic appendix showing adult pinworms inside the lumen and one worm in the mucosal layer of the appendix but no active inflammation (*Fig.* 1)
6	19	Central abdominal pain for 12 hours which settled in the right iliac fossa, associated with nausea and vomiting. Temp., 38·3° C. Tenderness with rebound in the right iliac fossa	Normal appendix	Pinworms in the lumen but no local inflammation
7	25	Had an attack of acute appendicitis which settled on conservative treatment but continued to have episodes of right iliac fossa pain lasting a few hours. Elective appendicectomy	Large swollen appendix with evidence of previous infection	Rather early acute appendicitis affecting all coats; lumen contained disintegrating worms
8	69	Admitted with acute sickness, vomiting, and abdominal pain of 2 days' duration. Temp., 37·7° C, with tenderness and rebound in lower abdomen	Purulent free fluid and gangrenous perforated appendix	Acute on subacute peritonitis with pieces of partly calcified worms in serosa

Preoperative investigation is unhelpful in this condition since the eggs are not passed in the stools and eosinophilia is an uncommon finding (Tolstedt, 1968). Often the diagnosis is made only at histological examination. Postoperatively the patients are still infested with pinworms and we strongly recommend that the patients should be given a suitable antihelminthic and that all other members of their family should also be treated.

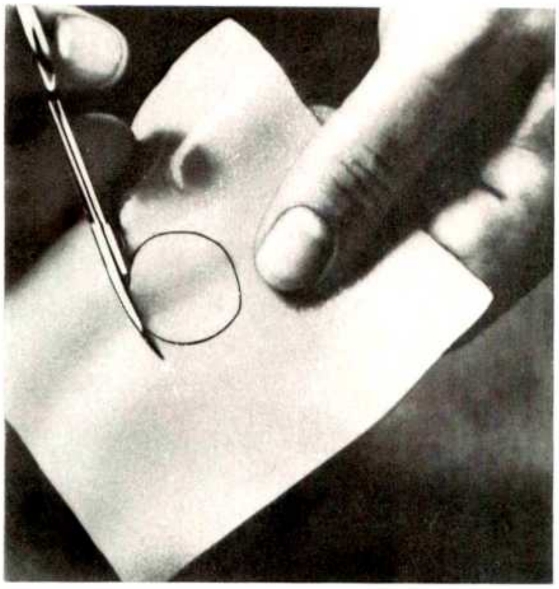
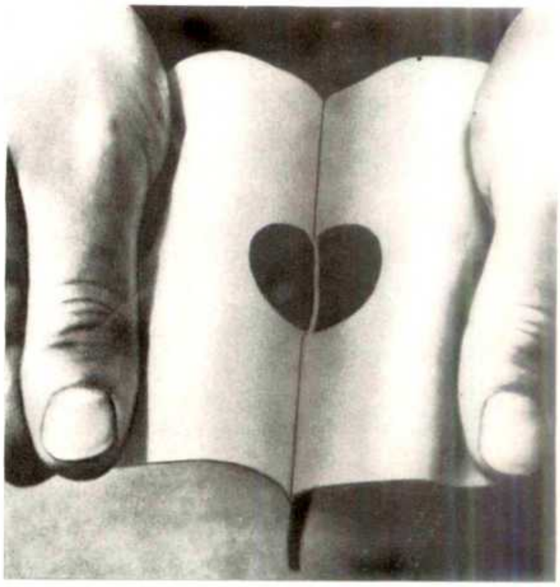
New from Squibb





Stomahesive

to provide comfort and protection in

Stomahesive
has been specifically designed to firmly adhere and mould to skin surfaces even when wet and excoriated.

Stomahesive
facilitates healing of excoriation and preserves the integrity of peristomal and perifistular skin.

ileostomy ileal conduit, colostomy, fistulae.

Stomahesive
provides a comfortable leak-free seal between appliance and skin.

Stomahesive is available for prescription on N.H.S. Form E.C.10.

Stomahesive
is prepared as a 10cm × 10cm square from gelatin, pectin, sodium carboxy methylcellulose and polyisobutylene. The exposed surface is protected by an impermeable polythene film.
Stomahesive must fit closely to the stoma. A cutting guide is provided.

UBRETID®
distigmine bromide

maintains smooth muscle tone
prevents urinary retention or intestinal atony

UBRETID inhibits cholinesterase for a full 24 hours, giving prolonged improvement in smooth muscle tone. Thus, with minimum inconvenience to staff or patient, a normal pattern of micturition and defaecation can usually be re-established without the discomforts of catheters or enemata. Where indwelling catheters are unavoidable, **UBRETID** will maintain bladder tone, reduce residual urine volume and encourage normal bladder function when the catheter is withdrawn.
Full details of **UBRETID** ampoules and tablets are available upon request.

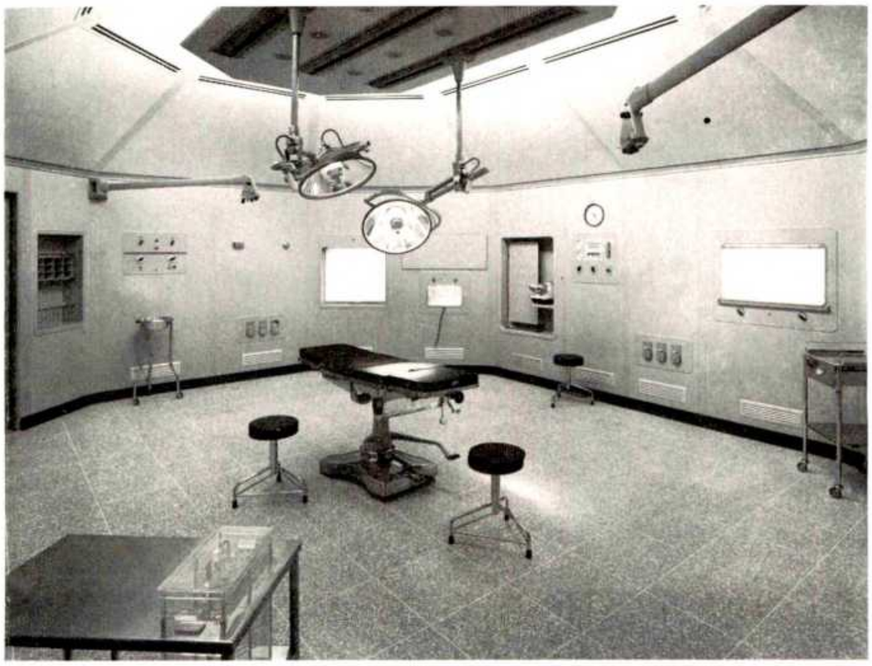
AN OPERATING ROOM FOR THE WORLD

FROM VENESTA HOSPITAL SYSTEMS LIMITED



Interior View of Venesta Modular Operating Theatre

The Venesta Modular Operating Theatre System has been produced as a basis for designing operating theatre suites to give a superior total surgical environment. Many installations have now been completed, and others are in progress, in hospitals in many parts of the world. Users welcome and appreciate the many advantages of a Venesta suite.

The nucleus of the system, the Venesta Modular Operating Theatre, was created following an in-depth study of the many functional requirements involved and represents a milestone in hospital design. The octagonal shape makes for efficient air conditioning whilst affording a most congenial working area for the surgeon and his team. Wall-mounted, specially designed equipment, e.g. diathermy, suction, etc., is serviced via rear-access without disturbance to the aseptic atmosphere within the theatre. The walls are formed by Melamine coated sandwich panels, easy to keep clean, very durable and pleasing to the eye. The general lighting unit illuminates the theatre indirectly thereby eliminating dazzle. Many other sensible features are incorporated. A lifespan in excess of that of conventional theatres is to be expected since new equipment of all types can be very easily incorporated in the structure.

The Venesta System is so flexible that it can provide the simplest single-theatre suite or the most complex multi-theatre suite. The theatre itself is available in ten different sizes to suit all surgical requirements. The system is equally applicable to new hospital developments and the upgrading of existing hospital facilities.

The capital costs involved are competitive with conventional theatre installations. The running costs, by virtue of the superiority of the total design, are significantly less than those of conventional installations.

SHORT NOTES OF RARE OR OBSCURE CASES

HUMAN TOXOCARIASIS (VISCERAL LARVA MIGRANS) CAUSING AN ABSCESS OF THE RECTUS SHEATH IN AN INFANT

By RICHARD W. GRIFFITHS*
HAMMERSMITH HOSPITAL, LONDON

SUMMARY

A patient is described with an abscess of the rectus sheath associated with the clinical features and operative findings of toxocariasis (visceral larva migrans).

Few cases of this condition are ever submitted to laparotomy, and the complication of rectus sheath abscess has not previously been reported. A brief review of the literature is given in order to outline the salient features of the condition.

HUMAN toxocariasis is rare, it being mainly a disease of cats and dogs. In 1964 Woodruff and Thacker found that 20 per cent of dogs and 22·7 per cent of cats in the home counties had *Toxocara canis* ova in their stools. However, 6 years later there were only 2·5 per cent infected dogs in the same area, probably as a result of deworming (Woodruff, 1970). Thus, the present main source of infection is the cat and the puppy prior to deworming.

The first report by Zuelzer and Apt (1949) of human visceral lesions with eosinophilia, and the finding of larvae in the liver by Mercer, Lund, Bloomfield, and Caldwell (1950) and Beaver, Synder, Carrera, Dent, and Lafferty (1952), led to many patients being diagnosed by exclusion and inference rather than by biopsy and histology. However, larvae and the classic eosinophilic infiltration and surrounding cell damage have been demonstrated on several occasions (Behrer, 1951; Beaver and others, 1952; Nichols, 1956; Ashton, 1960).

It is generally regarded as a benign condition which is protracted in its course, but the first lethal case describing granulomata in the lungs, heart, liver, and kidneys was reported by Brill, Churg, and Beaver (1953), and other deaths have been recorded by Moore (1962) and Schoenfield, Ghitric, and Rosen (1964).

Toxocara infestation appears to affect predominantly the age-group 1–5 years, and because it is acquired by puppies in utero it is more usual for human infestation to originate from the puppy than from the older dog. Beaver and others (1952) gave 3 clear case reports of young children, all of whom were submitted to laparotomy. In 2 of these cases the liver was seen to contain numerous whitish plaques which were biopsied; in both cases microscopy showed massive eosinophilic cell infiltration with some plasma and epithelioid cells, with necrosis of hepatic parenchymal cells. In only 1 case were larvae of *Toxocara canis* isolated. Woodruff, Ashton, and Stott (1961) emphasized the difficulty of finding larvae, and reported that only after cutting 100 sections was the larva found from the toxocaral lesion in the eye of a 5-year-old boy. Woodruff (1970) also emphasized the value of the *Toxocara* skin test and the fluorescein antibody test. The incidence of positive reactions in apparently healthy persons is 2 per cent, but the test remains positive for many years and therefore if it is positive it may not indicate present active infection. Indeed, isolation of larvae from either biopsy material or the patient's faeces is exceedingly uncommon, so that in many reported cases the diagnosis is presumptive (Shrand, 1964; Huntley, Costas, and Lyerly, 1965).

While in most cases laparotomy may not be deemed justified to clarify the diagnosis, in cases of obscure but intense eosinophilia liver biopsy may be of value and, in fact, produced evidence of larvae in 4 out of 10 patients in a series published by Snyder (1961). Toxocariasis in the human may reasonably be regarded as the correct diagnosis if the appearance of the liver biopsy is as described by Beaver and others (1952) in a patient with eosinophilia of over 30 per cent in the peripheral blood, especially in a child aged 1–5 years who plays with a dog or cat or is known to eat dirt (pica) from that animal's play area. It is rare for the pathologist to find the larvae in tissue sections because the larvae die in the tissues without reaching adult form.

The patient reported here is unusual because he had an abscess within the rectus sheath which appeared to originate from a parasite infection in the left lobe of the liver. His anaemia and eosinophilia which are so common in human toxocariasis favour the diagnosis (Dickson and Woodcock, 1959).

CASE REPORT

A 22-month-old male was admitted on 16 May, 1972, as an emergency. The patient's mother commented that for 1 week he had had abdominal pain and occasional vomiting and in the past few days an upper abdominal swelling had appeared. Apart from frequent coughs and colds he had been otherwise well from birth. The family had a 2-year-old pet dog with which he played but the child had not been seen to eat dirt.

On admission the patient's temperature was 37·5° C. which settled to normal in 24 hours. He was a well-nourished child and was not jaundiced and there were no enlarged lymph-nodes. The spleen was not palpable. The liver was just palpable, firm, and smooth. In the epigastrium to the left of the midline there was a firm tender swelling, 5 × 3·8, cm., which was not mobile on respiration and was not fluctuant.

---

* Present address: St. Catherine's Hospital, Birkenhead, Cheshire.

The results of the relevant haematological investigations are shown in *Table I*. The erythrocyte-sedimentation rate was 16 mm. in 1 hour, no ova or parasites were found in the stools, and the Casoni test was negative. The immunoglobulins were raised when compared with the normal values for a 22-month old child: IgG 11 g. per litre (normal 3–11 g. per litre), IgA 1·5 g. per litre (normal 0·1–0·8 g. per litre), and IgM 1·2 g. per litre (normal 0·2–1·0 g. per litre). The *Toxocara* skin test was negative. The bone-marrow showed an active cellular marrow in which the myeloid : erythroid ratio was within normal limits; 20 per cent of the total cells were eosinophils, more than half of which were mature, the remainder being eosinophil myelocytes (6 per cent) and promyelocytes (2 per cent).

Table I.—RESULTS OF THE HAEMATOLOGICAL INVESTIGATIONS

DAY OF INVESTIGATION	HAEMOGLOBIN (per cent)	WHITE-BLOOD COUNT	
		Total	Eosinophil (per cent)
1	68	19,600	40
2	65	17,200	44
9	108*	12,400	56
19	92	15,700	28
27	84	21,000	34

* After transfusion.

A skeletal survey and liver scan were normal.

Operation was postponed for 5 days because of a severe cough. At this time his chest radiograph showed inflammatory changes in both lung fields. He received a 5-day course of phenoxymethylpenicillin on the presumptive diagnosis that the lung changes were due to an allergic eosinophilic pneumonitis, although there was no clinical evidence of bronchospasm.

Laparotomy was performed after a blood transfusion. Under the anaesthetic palpation revealed that the epigastric mass had become considerably smaller but was still present.

The abdomen was opened through a left upper paramedian incision. The rectus sheath and the rectus muscle were found to be oedematous. Between the muscle and the posterior rectus sheath there was a small quantity of thin white-yellow pus (which proved sterile on culture, and no acid-fast bacilli were seen). Frozen section of this part of the rectus sheath showed a lymphocyte reaction, with only occasional eosinophils and plasma cells. On opening the peritoneum there was no free fluid but the omentum was adherent with a white-grey nodule in the left lobe of the liver. The liver was of normal size but studded with numerous white-grey nodules between 0·5 and 1·5 cm. in diameter which were solid when incised for biopsy. The spleen was slightly enlarged and there were many enlarged lymph-nodes at the coeliac axis. There were six areas of intussusception involving the small bowel, and while there was one yellow nodule on the peritoneal coat of the small bowel at the site of one of the intussusceptions the bowel wall was not thickened. The intussusceptions were both antegrade and retrograde. The omentum and peritoneum did not contain nodules.

Frozen section of the liver nodules showed 'eosinophilic granuloma' (lymphocyte and intense eosinophil infiltration). The postoperative course was uneventful and the patient was discharged on the tenth day. He was well a few weeks later and the swelling had not recurred.

The histological report stated that the liver showed an intense eosinophilic infiltration equivalent to an eosinophilic abscess. Histiocytes were not seen and no definite parasites could be identified, although some foreign material which was not chitin was present. The material taken from the rectus sheath was more granulomatous in nature and contained only a few eosinophils but showed a well-marked histiocytic reaction, including an occasional small giant cell. Again parasite remnants were not seen. The lymph-glands showed reactive hyperplasia only.

DISCUSSION

There is no record in the literature of eosinophilic granuloma affecting the liver; it usually affects the stomach or bowel and is rarely seen in association with such intense eosinophilia in an otherwise fit child. Eosinophilic granuloma is also a condition of adults. Good reviews of the features of eosinophilic granuloma are given by Ureles, Alschibaja, Lodico, and Stabins (1961) and Salmon and Paulley (1967).

In a series of 57 patients with a tentative diagnosis of 'visceral larva migrans' Huntley and others (1965) showed that in 34 patients (children between 1 and 5 years) with an eosinophilia greater than 30 per cent only 1 gave a positive reaction when sera were tested for the *Toxocara* antigen. In fact, the evidence that they presented to suggest that their patients were suffering from toxocariasis is slight. None of the patients was submitted to laparotomy or liver biopsy. They did find that half the patients possessed precipitating antibodies to blood-group substances A and B and that the total gammaglobulins were significantly elevated in just over half the series (especially the IgM fraction).

An editorial in the *Lancet* (1972) stated that 'the diagnosis is suspected from the clinical features . . . with persistent eosinophilia; only occasionally is it possible or necessary to confirm the diagnosis by biopsy or demonstration of larvae in tissue sections; and the presumptive diagnosis may be assisted by the results of a *Toxocara* skin test'.

In the patient reported here who presented with a sterile abscess of his rectus sheath associated with an intense eosinophilia (peripheral blood and bone-marrow picture) and hepatic lesions (macroscopic and microscopic), the diagnosis of human toxocariasis was made. The difficulties in diagnosis are obvious, for few cases of this condition are submitted to laparotomy, thus enabling direct liver biopsies to be taken as in this patient.

Acknowledgements.—My thanks are due to Professor O. P. Gray and Mr. Hugh Jones, under whose care this patient was admitted, for permission to publish details of the case, and to Professor James Calnan for his help and encouragement.

PYLORIC STENOSIS: HOLD-UP OF ENTERIC COATED ASPIRIN TABLETS

BY F. C. HARRIS*
MUSGROVE PARK HOSPITAL, TAUNTON, SOMERSET

SUMMARY

The case is presented of a 68-year-old woman with adult hypertrophic pyloric stenosis who ingested 66 enteric coated 650-mg. aspirin tablets over the course of 11 days immediately prior to her admission to hospital. Most of these tablets remained intact in the hugely dilated obstructed stomach and were recovered at emergency gastrotomy. The mechanism of disintegration of enteric coated tablets and the possible consequences of *en masse* disintegration of these ingested tablets are discussed.

ALTHOUGH reports have occurred of ingested enteric coated tablets being recovered whole in the stool (Pirnie and Staffurth, 1961; Wynn and Landon, 1963) no report has been found in the English literature of intact enteric coated tablets accumulating in a stomach over the course of several days. This report describes a patient in whom the accumulation of tablets reached such a proportion as to constitute a potentially life-threatening state.

CASE REPORT

The patient was an intelligent 68-year-old woman who had been known for 11 years to have rheumatoid arthritis affecting mainly her hands, wrists, and knees. Her arthritic pains had been well controlled with aspirin and she had been accustomed to taking 6 enteric coated aspirin tablets daily for more or less the whole of the 11 years. There had never been recourse for her to commence steroids nor had she ever taken indomethacin or phenylbutazone.

There had been no remote antecedent history of upper-gastro-intestinal discomfort, but 2–3 months before presentation she had developed anorexia and general malaise and in a short period she had lost 6 kg. in weight. One month before presentation she had begun experiencing aching epigastric pain unrelated to meals, epigastric fullness, nausea, bitter regurgitations at night, and foul flatulence, and she had had one large vomit of stale porridgy material 3 days before presentation.

In the belief that the epigastric pain might have been due to her aspirin ingestion the patient had stopped taking the tablets shortly after the onset of the epigastric pain. However, stopping the tablets allowed no improvement in the epigastric pain but merely permitted an exacerbation of rheumatoid joint pain to occur, and so 11 days prior to presentation she had resumed taking 6 enteric coated aspirin tablets each day, but now, however, there was no attendant improvement in the arthritic pain.

At this stage the patient was urgently referred to the Out-patients' Department of Musgrove Park Hospital, Taunton, where the presence of a marked succussion splash and a moderately distended abdomen was noted. The patient was admitted to hospital and an emergency barium-meal examination was performed with remarkable findings (*Figs.* 1, 2).

A large-bore nasogastric tube was passed and a small quantity of thick porridgy material of acid reaction was aspirated. No attempt was made to irrigate the stomach for fear of dissolving the tablets *en masse*.

The serum salicylate level on admission was 2·6 mg. per 100 ml. and the haemoglobin, P.C.V., plasma proteins, and serum electrolytes were all normal. The patient, however, appeared clinically slightly dehydrated and therefore was intravenously rehydrated overnight.

The following day laparotomy was performed. The hugely dilated stomach was opened and the contents were evacuated. From the slurry thus obtained 61 intact enteric coated aspirin tablets and several enteric shells of disintegrated tablets were recovered (*Fig.* 3).

The pylorus was found to be greatly reduced in diameter and would only admit the tip of a haemostat, but there were no signs of active pyloric or duodenal ulceration or of chronic fibrosis or malignancy.

Total vagotomy and posterior gastrojejunostomy were performed from which the patient made an uneventful recovery to be allowed home 18 days after admission.

DISCUSSION

The radiological and clinical findings were consistent with a diagnosis of adult hypertrophic pyloric stenosis. In this condition the resting gastric *p*H is variable and there may be hyperacidity or achlorhydria (Keynes, 1965).

The patient had ingested 66 enteric coated aspirin tablets over an 11-day period immediately prior to admission; 61 of these tablets containing nearly 40 g. of aspirin were recovered intact at gastrotomy. The accepted fatal dose of aspirin for an adult lies between 24 and 30 g. (*Extra Pharmacopoeia*, 1967).

The enteric coating employed in the manufacture of these tablets comprises a layer of cellulose-acetate-phthalate (C.A.P.) and the integrity of the coating is *p*H dependent in aqueous media, being unaffected by digestive enzymes. The critical *p*H for the coating is 6·0; below this *p*H the layer is stable but above this *p*H the coating softens, swells, and disintegrates (Payne, 1966). If, however, there is a flaw in the coating then the contents of the tablet may be released in any aqueous medium independently of pH. Such flaws may occur in manufacture if the coating is not quite entire but all batches are, in fact, meticulously sample-tested before distribution to retailers in order to ensure the highest possible quality of the coating. However, flaws in the form of chips off the coating occur more commonly after distribution and are caused by mechanical trauma such as may be occasioned by agitation of the tablets within a bottle (Medical Department, Eli Lilly & Co. Ltd., 1973).

---

* Present address: Bristol Royal Infirmary.

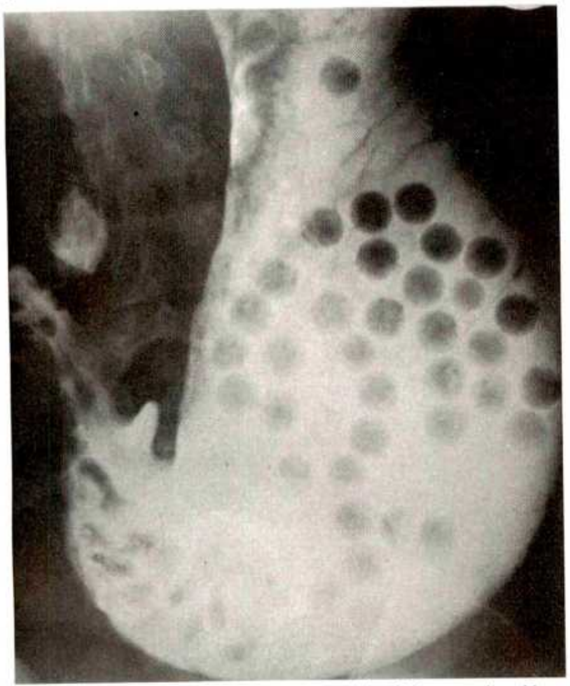

FIG. 1.—Barium-meal film showing the filling defects produced by the ingested aspirin tablets.

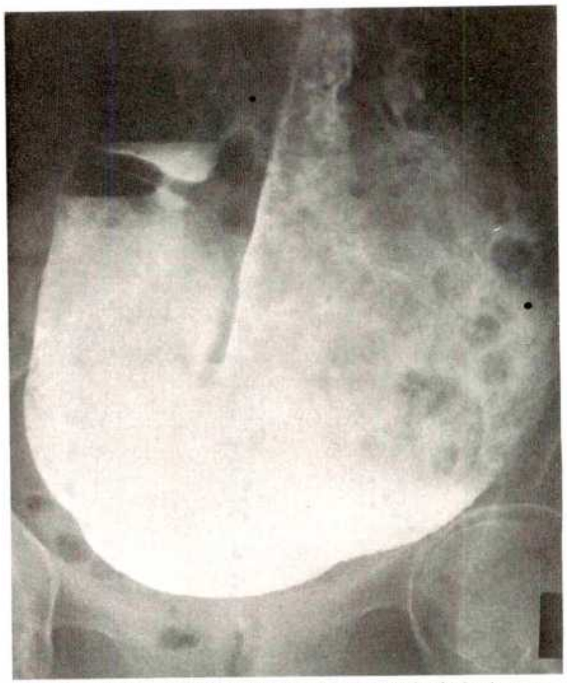

FIG. 2.—Barium-meal film showing the degree of pyloric obstruction, the extent of gastric dilatation, and the filling defects.

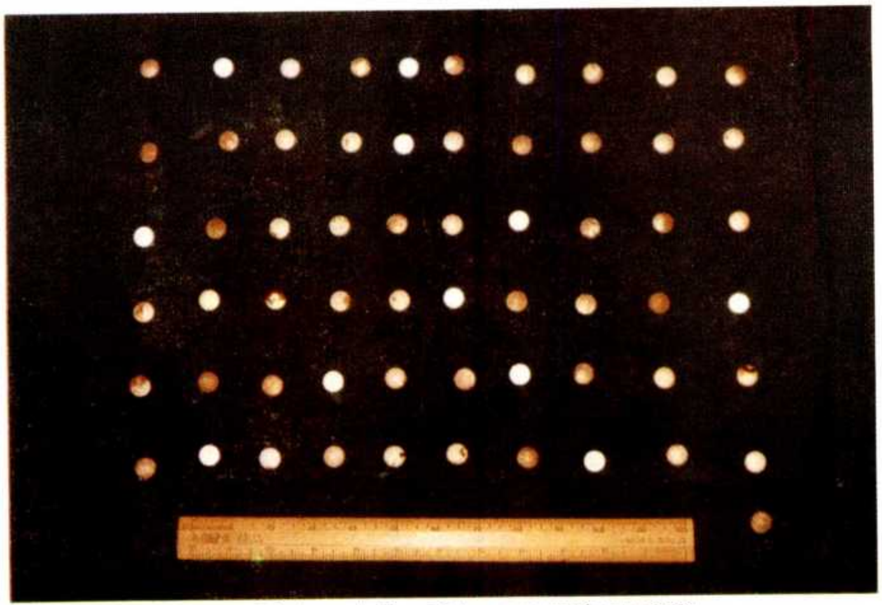

FIG. 3.—The ingested tablets which were recovered at gastrotomy.

The recovered intact ingested tablets in the present case have been subjected by the manufacturers to the B.P. enteric coated tablet disintegration test (*British Pharmacopoeia*, 1968). The tablets have been found to satisfy the B.P. requirements for enteric coated tablets such that they are capable of withstanding an acid environment without disintegration and yet will undergo disintegration subsequently if immersed for half an hour in a buffer solution of *p*H 6·8.

The plasma salicylate level is dose-dependent and 1 g. of enteric coated aspirin can be expected after an absorption delay of 8 hours to give a level of 7–8 mg. per 100 ml. which then falls to near zero after a further 8 hours (Ansell, 1962).

To account for the trace of salicylate found in the sample of plasma taken on admission, at least one of the ingested tablets must have disintegrated within a short period prior to the patient's admission. In fact, remnants of 5 tablets were recovered from her stomach and it would seem likely that each of these 5 tablets possessed a flaw in its C.A.P. coating and underwent disintegration shortly after each was ingested, because had disintegration of the coating been caused by a rise in *p*H of the gastric contents, then all 66 tablets would have been affected equally.

The fact that 61 tablets, which later in the laboratory proved still capable of disintegration after half an hour of immersion in a buffer solution of *p*H 6·8, remained intact in a stomach for up to 11 days indicates that neither did these recovered tablets possess any flaws in their coating nor could the stomach *p*H have risen above the critical *p*H of 6·0 for any significant length of time.

Stafforth in 1953 showed that the stomachs of 8 patients with upper gastro-intestinal disorders could be maintained at an alkaline *p*H for at least half an hour by the administration of a single 8-g. dose of sodium bicarbonate. Sippy in 1915 showed that 'in cases of high grade pyloric obstruction' all free hydrochloric acid can be neutralized by the administration of 6·5 g. (100 grains) of sodium bicarbonate at hourly intervals.

It is very fortunate indeed that the patient of this present report did not seek to relieve her 'indigestion' by taking the hitherto popular household remedy of a teaspoonful or two of sodium bicarbonate. The 6–12 g. of sodium bicarbonate so taken would almost certainly have raised her stomach *p*H high enough for a sufficient length of time to allow most if not all the ingested tablets to disintegrate within a short period perhaps with serious results because aspirin is rapidly absorbed even by gastric mucosa.

Acknowledgements.—My thanks are due to Mr. R. D. Rowlands under whose care the patient was admitted and to Mr. J. B. Grundy of the Medical Department of Eli Lilly & Co. Ltd. for his help in arranging the testing of the tablets.

CARCINOMA ARISING IN A DUPLICATED COLON

CASE REPORT AND REVIEW OF LITERATURE

BY M. L. HEIBERG, K. G. MARSHALL, AND H. S. HIMAL*

DEPARTMENTS OF PATHOLOGY AND SURGERY, ROYAL VICTORIA HOSPITAL AND MCGILL UNIVERSITY, MONTREAL, CANADA

SUMMARY

A case of primary adenocarcinoma arising in a duplication of the right colon is reported. The unusual clinical presentation and management are discussed.

DUPLICATIONS of the gastro-intestinal tract are many and variable, the most common sites being in the oesophagus and ileum. The ascending colon is infrequently involved. Even less frequent is malignant change in these anomalies. This paper reports a case of adenocarcinoma arising in a duplicated right colon.

CASE REPORT

Mrs. A. C., aged 50 years, had been examined regularly by her gynaecologist for fibroids of the uterus. She was well until December, 1972, when she developed lower abdominal pain, which was sharp, non-radiating, and associated with anorexia, nausea, vomiting, and diarrhoea. On physical examination in hospital a large, 5 × 10 × 5 cm., tender and mobile mass was palpable on the right side of the abdomen. The haematocrit was 39 per cent and the white-blood count was 8900 per c.mm. The clinical impression was that of infarcted uterine fibroid or torsion of an ovarian cyst. At surgery a firm perforated caecal mass was noted. Firm mesenteric lymph-nodes were also present. A right hemicolectomy was performed with end-ileostomy and colostomy. Ileocolostomy was performed on the fifteenth postoperative day. Recovery was uneventful except for a wound infection which responded to conservative management.

PATHOLOGY.—The specimen consisted of a resected distal ileum, appendix, caecum, and ascending colon. At the level of the ileocaecal valve but situated posterolaterally there was a round mass measuring 6 × 8 cm. which when opened contained thick brownish material (*Fig.* 1). The cyst wall was flattened over most of its surface except at its attachment to the caecal wall, where a raised irregular surface (2·5 × 3·0 cm.) was noted. On the caecal side the mucosa appeared unremarkable except at the level of the adherent cyst wall, where it was thickened and contained a small (0·4 cm.) opening which when probed entered the cyst cavity (*Fig.* 2). Sections through this area revealed invasive adenocarcinoma (*Fig.* 3). The mesenteric nodes also contained tumour cells. Sections through the smooth cyst wall showed muscle layers and a flattened mucosa, consistent with a duplication. There was also evidence of chronic inflammation and fibrosis.

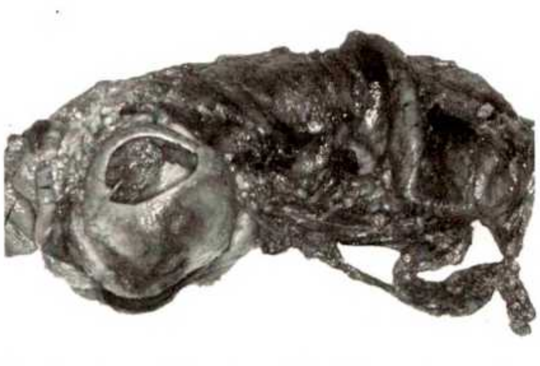

FIG. 1.—Resected specimen demonstrating the duplication adjacent to the posterolateral aspect of the caecum.

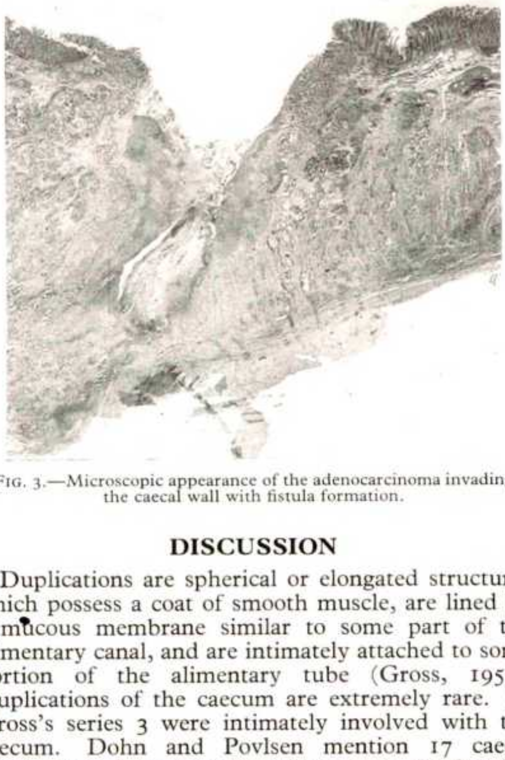

FIG. 3.—Microscopic appearance of the adenocarcinoma invading the caecal wall with fistula formation.

DISCUSSION

Duplications are spherical or elongated structures which possess a coat of smooth muscle, are lined by a mucous membrane similar to some part of the alimentary canal, and are intimately attached to some portion of the alimentary tube (Gross, 1953). Duplications of the caecum are extremely rare. In Gross's series 3 were intimately involved with the caecum. Dohn and Povlsen mention 17 caecal duplications in their review up to 1951. Perforation of a colonic duplication is rare and can present as peritonitis (Reid, 1969). Neoplasia arising in a duplication of the colon has only been reported twice in the English literature. Tamoney and Testa (1967) described a case in a 61-year-old female who presented with nausea and abdominal pain. Barium-enema examination revealed a large filling defect consistent with a tumour of the caecum, and right hemicolectomy and ileotransverse colostomy were performed. Pathological analysis of the specimen demonstrated a duplication of the caecum in which was present an infiltrating adenocarcinoma. Larizadeh and Powell (1965) described the case of a 44-year-old female who developed nausea and abdominal pain. Abdominal examination revealed a 7·5-cm. mass to the right of the umbilicus. Barium-enema examination filled a tract outside the right colon. At laparotomy a mass was found to involve the transverse colon. A right hemicolectomy and ileotransverse colostomy were performed. Pathological analysis revealed a duplication opening into the ileocaecal area of the intestine and running along the lateral aspect of the ascending colon to the hepatic flexure and terminating in a neoplastic mass in the mid-transverse colon. Histological analysis demonstrated a squamous-cell carcinoma.

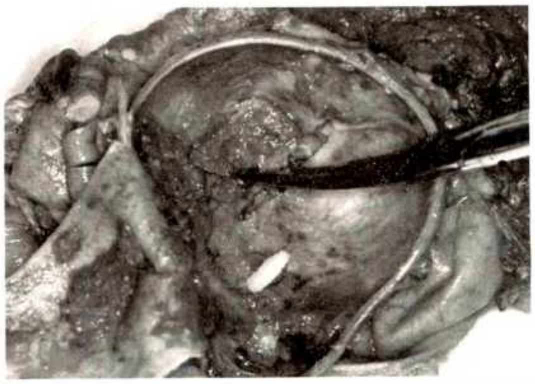

FIG. 2.—Site of perforation of the adenocarcinoma in the duplication.

The present report discusses the third case to be reported in the literature of a carcinoma arising in a duplication of the colon. This patient was asymptomatic until obstruction and perforation developed. It is postulated that the carcinoma arose in the medial wall of the duplication and penetrated into the caecum, resulting in obstruction and perforation. Because of the hazards of performing an intestinal anastomosis in the presence of perforation and obstruction, the distal ileum, caecum, and ascending colon were resected and an ileostomy and colostomy were performed. Two weeks later the ileostomy and colostomy were taken down and ileotransverse colostomy was performed with no adverse sequelae.

THROMBOSIS OF THE SUBCLAVIAN-AXILLARY ARTERY FOLLOWING RADIOTHERAPY FOR CARCINOMA OF THE BREAST

By G. E. Mavor, A. T. Kasenally, D. R. Harper, and P. W. H. Woodruff.
ABERDEEN ROYAL INFIRMARY

SUMMARY

Two cases of subclavian-axillary-brachial artery occlusion following irradiation damage are reported. Both followed radiotherapy for carcinoma of the breast at intervals of 11 and 26 years respectively.

ARM morbidity following mastectomy, particularly when associated with radiotherapy, is well known and is compounded of many factors including axillary and subclavian vein thrombosis, ablation or destruction of arm lymphatic drainage vessels, and poor incision placements with subsequent scarring. A less well-known cause is serious ischaemia resulting from occlusion of the main artery of the limb.

CASE REPORTS

Case 1.—J. W. M., a woman aged 65 years, was referred to the Vascular Clinic of Aberdeen Royal Infirmary on 11 Jan., 1972, with a 3-month history of right forearm pain and marked cyanosis and numbness of her right hand. Eleven years previously a right mastectomy had been carried out in the treatment of carcinoma of the breast. Surgery had been followed by radiotherapy. Using a 250-kV. Marconi therapy tube at 10 MA., with a triple Thoraeus filter and a focal skin distance of 50 cm., a central dose of 4274 r had been administered to the breast area in two opposing tangential fields, each 15 × 10 cm., over a period of 19 days. The supraclavicular and axillary fields, the anterior one being 25 × 12·5 cm. and the posterior one 15 × 10 cm., had been given a central dose of 3750 r and a maximum dose of 4440 r over the same period of time using a Thoraeus filter. A severe skin reaction had followed radiotherapy but this had settled with time and local ointments. Since the initial therapy there had been no clinical evidence of recurrence or metastases.

Three months prior to her present referral the patient had noted the gradual onset of paraesthesia and an aching pain in her arm when in use. These symptoms were promptly relieved by rest. Her symptoms had gradually become worse and she had also developed numbness, coldness, and cyanosis of the right hand.

On examination relevant findings were related to the right breast area and right arm. There was no evidence of local recurrence or metastases in relation to her previous right breast carcinoma. There was extensive telangiectatic skin changes over the irradiated area (*Fig.* 1). The left arm blood-pressure was 198/104 mm. Hg and the pulse-rate was 84 and regular. The right arm blood-pressure was not recordable. The right arm was markedly wasted. There was no swelling and movements were full. All pulses distal to the subclavian were absent. The haemoglobin was recorded twice and was 16·2 (110 per cent) and 15·2 (104 per cent) g. per 100 ml. The corresponding P.C.V.'s were 55 and 44 per cent. The E.S.R. was 10 mm. fall in the first hour. Serum urea, electrolytes, sugar, and proteins were normal and the serum cholesterol was 276 mg. per cent. A chest radiograph was normal. A right subclavian arteriogram showed segmental occlusion of the upper brachial artery of about 4 cm. in length. The collateral circulation was poor in that there were no large vessels, but distal filling was satisfactory (*Fig.* 2 A).

Treatment consisted of exposure of the axillary and brachial arteries and the insertion of a 14-cm. autogenous vein by-pass graft, consisting of reversed right long saphenous vein. The occluded portion of the brachial artery was fibrotic and cord-like. There was no notable irregularity, plaques, or calcification. No biopsy was taken. There was no evidence of atherosclerosis at the sites of the anastomoses, but the proximal axillary artery was more thick-walled than expected. Soon after surgery the patient regained the right brachial and radial pulses and went on to make a straightforward recovery. Two years after surgery an arteriogram showed the graft to be satisfactory (*Fig.* 2 B), and the patient had no complaints referable to the arm or hand. At follow-up examination the haemoglobin was 15·3 g. per 100 ml. (105 per cent) with a P.C.V. of 46 per cent. Her red-cell mass was within normal limits.

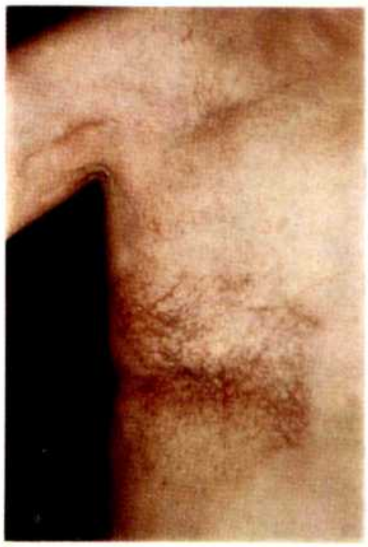

FIG. 1.—*Case* 1. Extensive post-irradiation telangiectatic skin changes. Skin incisions are also visible.

Case 2.—H. D., a woman aged 70 years, was seen on 12 Jan., 1971, with a 6-month history of increasing discomfort in her left arm, hand, and fingers.

The relevant feature of her past medical history was that 26 years previously she had undergone a left radical mastectomy followed by radiotherapy. Using a 250-kV. Marconi therapy tube at 10 MA., with a triple Thoraeus filter and a focal skin distance of 60 cm., a central dose of 3000 r in 12 days had been applied to the breast area in two opposing tangential chest fields, each 20 × 10 cm.

The same dosage had been applied to a similar area of both the supraclavicular and axillary fields. She had had a severe skin reaction but this had subsided with topical treatment. Over the past 26 years, apart from slight swelling and residual weakness in her left arm, she had been in good health. Six months before her present admission she had noticed that her left arm and hand were becoming stiff and painful. Exercise had made these complaints worse and discomfort had prevented her from playing the piano. She had also noticed her left hand and fingers becoming cold and discoloured.

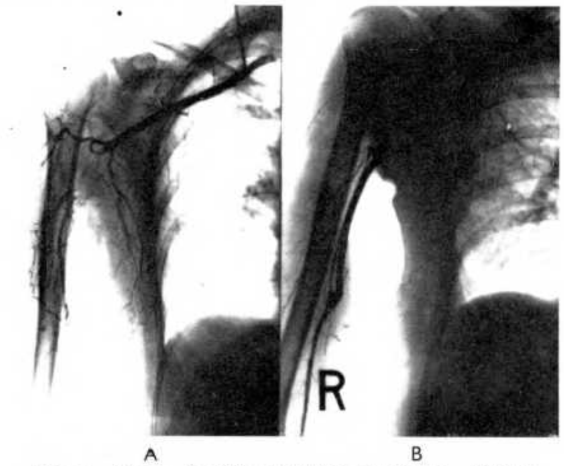

FIG. 2.—*Case* 1. A, Right subclavian arteriogram. There is segmented occlusion of the upper brachial artery. The collateral circulation is poor but distal filling is satisfactory. B, Follow-up right subclavian arteriogram after reconstructive surgery, showing the autogenous vein by-pass.

On examination relevant findings were limited to the left chest and arm. The right arm blood-pressure was 160/90 mm. Hg and the pulse 72 beats per minute and regular. The left arm blood-pressure was not recordable. There was no evidence of heart failure or cardiomegaly. The left radical mastectomy scar reached the left arm. Extensive telangiectatic skin changes were noted over the irradiated area on the left side of the chest. There was no evidence of recurrent carcinoma. There was marked restriction of abduction of the arm, and the arm, hand, and fingers were markedly cold. Coldness and pallor increased with exercise and the fingers showed early ischaemic changes. No subclavian, axillary, brachial, or radial pulse could be located. The haemoglobin was 14·7 g. per 100 ml. (101 per cent), blood-urea 24 mg. per cent, fasting blood-sugar 74 mg. per cent, and serum cholesterol 202 mg. per cent. The electrocardiogram showed minor ischaemic changes with possible subendocardial infarction. A chest radiograph showed fibrosis in the left upper zone with extensive post-irradiation bone damage in the left ribs, clavicle, scapula, and humerus (*Fig.* 3). A skeletal survey showed no metastatic deposits.

Arteriography showed that the left subclavian artery was obstructed immediately distal to the origin of the vertebral artery. Proximal to this the artery showed considerable irregularity and narrowing. No definite collateral circulation was demonstrated and no refilling of the artery occurred (*Fig.* 3). In the absence of evidence of distal reconstitution of the artery treatment was conservative.

DISCUSSION

From experimental and clinical studies it would seem that radiation injury to tissues and organs is in part mediated through damage to the fine vasculature (Rubin and Casarett, 1968). The capillaries, arterioles, and venules are particularly susceptible, and large and medium-sized arteries are damaged primarily through the involvement of the vasa vasorum networks in an irregular though widespread manner. The failing nutrition of the vessel wall leads to serious consequences as regards the integrity of the larger vessel, with sclerosis, atheromatous-like changes, narrowing, aneurysm formation, and occlusion being possible (Smith, 1961; Sams, 1965; Rubin and Casarett, 1968). Furthermore, because of the widespread nature of irradiation damage, it is unlikely that in the presence of narrowing or occlusion of an important artery an adequate collateral circulation can develop. It is surprising that there are so few reports in the literature of irradiation damage to medium and large arteries. Most of these have been cases of early rupture, usually complicated by infection (Marcial-Rojas and Castro, 1962). Pearson (1958) described coronary artery occlusion 6 months after irradiation of the chest for tumour. There are reports of aortic thrombosis (Thomas and Forbus, 1959), subclavian and innominate thrombosis (Heidenberg, Lupowitch, and Tan, 1966), femoral artery thrombosis (Gross, 1969), profunda stenosis (Pouliaf, Giannopoulos, and Frangagis, 1967), and bilateral common iliac artery stenosis (Johnson, Lane, Rains, O'Connell, and Ramsay, 1969), all following irradiation for various conditions. Some of these arterial effects may have been due to perivascular fibrosis. A recent case of femoral artery aneurysm has been described (Ross and Sales, 1972). No report can be found describing subclavian and axillary occlusion following irradiation in the treatment of carcinoma of the breast.

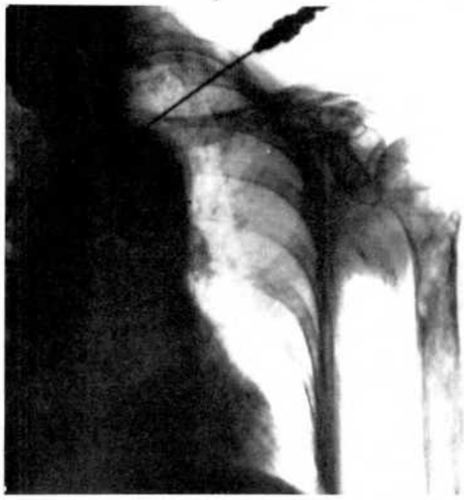

FIG. 3.—*Case* 2. Left subclavian arteriogram and chest radiograph. There is extensive post-irradiation bone damage to the ribs, clavicle, and humerus. The left subclavian artery is obstructed just beyond its origin. No collateral circulation and no distal filling are present.

The aetiology of occlusion in these 2 cases probably lies between traumatic thrombosis, a non-specific arteritis, atherosclerosis with secondary thrombosis, and irradiation damage. The possibility of trauma relates only to *Case* 2 in relation to the radical mastectomy. It is unlikely, however, that axillary artery thrombosis resulting from operative damage would be undetected for so long. The possibility of an arteritis is entirely speculative. If atheromatous, the lesions may be either primary or secondary to irradiation damage. Primary atherosclerosis is uncommon in the axillary-brachial artery. The only evidence of possible atherosclerosis elsewhere in either case is in relation to the coronary arterial system in *Case* 2. At operation in *Case* 1 the occluded segment of the brachial artery was uniformly sclerotic without atheromatous irregularity or calcification.

In both the cases reported here severe local skin reaction occurred and telangiectasis was extensive. In *Case* 2 where extensive bone damage was visible on radiography the X-ray dosage may have been excessive, but this can hardly have occurred in *Case* 1. A feature of both arteriograms is the absence of any reasonably sized collateral channels. Although surgical ligation of some of the available collaterals was probably undertaken in *Case* 2, the inadequacy of the collateral circulation is possibly inherent in the nature of the irradiation damage and no doubt accounts for the extent of the main vessel occlusion in *Case* 2, even though at that stage the occlusion was segmental and limited, and the severe ischaemia in *Case* 1.

It would appear that large and medium artery sclerosis following irradiation is slowly progressive, leading to final thrombosis not only long after the initial insult but at an extremely variable interval. The prognosis, which is related to the extent of the occlusion and the progressive peripheral ischaemia, is not good unless reconstructive arterial surgery is feasible.

REVIEWS AND NOTICES OF BOOKS

Diagnostic Bronchoscopy. An Introduction. Second edition. By PETER STRADLING, M.D. (Lond.), F.R.C.P., F.R.P.S., Royal Postgraduate Medical School, London. 10 × 7¾ in. Pp. 125+ix, with 166 illustrations. 1973. Edinburgh: Churchill Livingstone. £4.

DR. STRADLING is far too modest in calling this second edition of his book 'an introduction'. The manipulation of the bronchoscope, even by those experienced in its use, carries certain hazards, some minor and some major, such as damage to teeth, temporary interference with the airways to the lung, and severe haemorrhage during the taking of biopsies. This book lays down not only the principles but also the details of how to avoid such problems. Today bronchoscopists, by and large, employ general anaesthesia in preference to local anaesthesia; this in turn places great responsibility on anaesthetists, who will read with interest the excellent chapter on 'Manipulating the Bronchoscope' in which a clear explanation of the oxygen Venturi technique for ventilation of the lungs during the processes of suction, biopsy, and photography supplements the account given of the positioning of the head and chest during the examination and the introduction of the instrument.

The clear exposition of the normal anatomy, the abnormal appearances produced by pathological states, and distortions produced by them are described and illustrated by the most beautiful endoscopic photographs ever seen by the reviewer. The sketches which are placed alongside these photographs are helpful and clearly explained with an excellent economy in the wording.

This work will be of interest to those who practise bronchoscopy and to many others who do not realize what an important part the examination plays in the management of lung diseases both common and rare.

The production of the book is highly professional, and for the era in which it is offered is good value at £4.

Tumours of Childhood. A Clinical Treatise. By I. G. WILLIAMS, M.B., B.S. (Lond.), F.R.C.S. (Eng.), F.F.R., D.M.R.E., St. Bartholomew's Hospital, London. 8½ × 5½ in. Pp. 169+xii, with 38 illustrations. 1972. London: William Heinemann Medical Books Ltd. £3·25.

THIS book has been written by a radiotherapist of great clinical experience in the treatment of children with malignant disease, and the extensive knowledge which Mr. I. G. Williams acquired as Consultant Radiotherapist at the Hospital for Sick Children, Great Ormond Street, is reflected throughout this book. He has sought assistance from some of his colleagues for certain sections, such as the nursing aspects, advice to parents, and the co-ordination of treatment; the section on acute leukaemia has been written by Dr. Derek Crowther and that on intracranial tumours by Dr. E. W. Emery. Apart from this the rest of the book is the result of a vast amount of experience in a wide range of malignant disease, and Mr. Williams gives advice which will be of enormous value to paediatricians, surgeons, radiotherapists, and chemotherapists who have to deal with children with malignant disease.

As deaths from other causes decline those due to malignant disease become a more important proportion of the total, and there may also have been a small increase in malignant disease in childhood. The treatment of leukaemia, which probably accounts for almost half the deaths from cancer in childhood, is now well organized, but the management of other forms of malignant disease in children lags far behind, although much improvement has been achieved in the past 5 years. Surgery is still the most important form of treatment and the one most likely to produce a cure when total excision of the disease is possible. Unfortunately, many of the tumours of childhood are already so far advanced when first seen that complete excision is impossible, and it is for these that radiotherapy and chemotherapy offer the main hope of palliation and survival.

This book deals with all the main forms of cancer in childhood in a systematic fashion, giving detailed advice, particularly about radiotherapy and chemotherapy, illustrated by pertinent case reports. There is an excellent chapter on radiotherapy in general as applied to children, including its adverse effects and complications. Most of the types of chemotherapy in common use are also described, and this section is up to date in spite of the rapid changes which are taking place at the present time in the use of chemotherapeutic agents in the treatment of tumours of all kinds, and especially of neuroblastoma and nephroblastoma.

This book contains a vast amount of information the fruits of a very extensive clinical experience—presented in a modest and clear fashion. It is the best account of its subject which has yet appeared and is essential reading for all those who have to care for children with cancer; it cannot be too strongly recommended.

Planning of Surgical Centres. Second edition. By ERVIN PUTSEP, Stockholm. 8½ × 8½ in. Pp. 250. Illustrated. 1973. London: Lloyd-Luke. £6.

THIS is an excellent book dealing with the many facets of operating-theatre design. There is detailed consideration of many of the controversial aspects of design; in particular those factors which may affect postoperative wound infection. The facts are carefully marshalled to indicate which features of design appear to be based on good evidence and this in turn leads to the choice of the structural components of the theatre.

The structure of the theatre is considered both in relation to function and the effects on those working in the area. The author draws on experience in many different countries to present a book which is well written, carefully argued, and beautifully presented. It is unlikely that everyone will agree with its recommendations, but for those involved with the design of new centres it should be regarded as essential reading.

Pathology of Toxaemia of Pregnancy. By H. L. SHEEHAN, D.Sc., M.D., F.R.C.P., F.R.C.O.G., F.R.C. Path., Liverpool, and J. B. LYNCH, M.D., F.R.C.S. F.R.C.Path., Leeds. 9¼ × 6¼ in. Pp. 807 + viii. Illustrated. 1973. Edinburgh: Churchill Livingstone. £13.

IT is most fitting that much of the major work of such an eminent obstetric pathologist as Sheehan should be presented in book form. This has been coupled with an extensive review of the pathological features of toxaemia. Emphasis is placed on the importance of collecting autopsy material within a very few hours of death and this was done in a large number of cases of severe pre-eclampsia and eclampsia. Unfortunately the material is not suitable for electron microscopic studies. The very detailed recurrence of the lesions in organs will be of interest to all pathologists who are likely to deal with deaths from toxaemia. It is unfortunate that in spite of such detailed studies no clear light is thrown on the aetiology of this condition. One of the most recent and attractive theories is that of intravascular coagulation which is not supported by findings in the kidneys and pituitaries studied.

As well as an extensive list of references there is a useful appendix giving the summary of the recent literature for 1970–2. The clinician will not find much to help him in the prevention or management of toxaemia in this book, but for those interested in the pathology of pregnancy and in the aetiology of this fascinating condition this book is to be recommended.

Progress in Surgery. Edited by M. ALLGÖWER, Basel, S. E. BERGENTZ, Malmo, R. Y. CALNE, Cambridge, and U. F. GRUBER, Basel. 9¼ × 6¾ in. Pp. 131 + vii, with 37 illustrations. 1973. Basel: S. Kargar. £7·80.

Progress in Surgery is a title designed to entice all surgeons to peruse the contents, but unless he is a specialist he may be disappointed with this volume which deals with selected topics. Each topic is written by an authority in the field, and varicose veins, thrombo-embolism, and the present state of cardiac surgery are considered in detail. For the specialist this volume is a reference book with few illustrations but good references.

This slim volume is well written but will appeal only to a few surgeons interested in the specific topics.

Antenatal Diagnosis of Genetic Disease. Edited by A. E. H. EMERY, Edinburgh. 8¼ × 5¼ in. Pp. 169 + ix, with 23 illustrations. 1973. Edinburgh: Churchill Livingstone. £2·50.

THE importance of antenatal diagnosis of genetic disease is now related to the relaxation of the law on abortion. Advances in knowledge, particularly in relation to amniocenteses, provide a warning of genetic defects which may allow a decision on abortion. The medical and ethical problems surrounding this difficult area are considered in this volume which has a concise text and liberal references.

INDEX TO VOLUME 60

ALLARDYCE, M.: *See* MAVOR, G. E., jt. auth.
Alveolus, lower, carcinoma involving 85
Amoebiasis in children, surgical management of 623
Ampicillin, topical, effect of, on wound-infection rate after cholecystectomy 355
Ampulla of Vater and duodenum, carcinoma of 33
Amputation(s), lower-limb, investigation into spread of bacterial infection in 723
— stumps, method of supportive bandaging for 729
Amputees, lower-limb, functional and social review of 732
ANAGNOSTOPOULOS, D. I., and GORTVAI, PETER: Intracranial subdural abscess 50
Anastomoses, intestinal, aetiology of disruption of 461
— single-layer inverting, two-layer inverting, and everting, in rabbit colon, comparison of 453
— — and two-layer inverting intestinal, randomized prospective clinical trial of 457
ANDREWS, M. J., and PEARSON, F. G.: An analysis of 59 cases of tracheal stenosis following tracheostomy with cuffed tube and assisted ventilation, with special reference to diagnosis and treatment 208
Aneurysm(s), abdominal aortic, horseshoe kidney and 243

PAGE

Aneurysm(s), abdominal aortic, and peptic ulcer, association of, and its significance 302
— atherosclerosis and, formation in saphenous vein-graft 72
— of descending thoracic aorta, ruptured non-traumatic 885
— thoracic aorta, surgical treatment of, under temporary external by-pass shunt 597
— traumatic, of superficial temporal artery 530
ANGEL, J.: *See* WEAVER, P. C., jt. auth.
ANNIS, DAVID: A sterile 'use-once' clip applicator for skin closure 686
Anorectal suppuration: results of treatment and factors influencing recurrence rate 537
Antibody(ies) activity, heterophile, depression of immune responsiveness in breast and large-bowel tumours as measured by 352
— humoral, significance of, in localization of human malignant melanoma 443
Antral acidification, effect of, on acid secretion stimulated by pentagastrin 197
Aorta, descending thoracic, ruptured non-traumatic aneurysms of 885
— thoracic, surgical treatment of aneurysm of, under temporary external by-pass shunt 597
Aortic aneurysm, abdominal, horseshoe kidney and 243
— — — and peptic ulcer, association of, and its significance 302
Appendicitis, acute, leucocyte count in 618
Appendix, intussusception of 619
— pinworm infestation of 975
ARCHER, G. G.: *See* LASZLO, G., jt. auth.
Argentaffinoma, primary, of ovary 749
Arterial complications of polycythaemia vera 183
— disease, ABO blood groups in occlusive and ectatic 892
— — cystic, aetiology of 397
— embolism, review of 174 patients with 894
— embolus to upper limb 505
— sling tourniquet, use of, in surgical practice 594
— and venous grafts, cross-over femorofemoral, treatment of combined external iliac artery and vein injury, with temporary arteriovenous shunt 744
Arteriography, internal pudendal, after priapism 329
Arteriovenous shunt(s), temporary, treatment of combined external iliac artery and vein injury by cross-over femorofemoral arterial and venous grafts with 744
— — thrombosed external and internal, management of 381
Artery(ies), common to deep femoral (profunda femoris), reversed autogenous saphenous vein by-pass from 676
— external iliac and common femoral, closed injury of 679
— subclavian-axillary, thrombosis of, following radiotherapy for carcinoma of breast 983
— superficial temporal, traumatic aneurysms of 530
Arthritis of carpometacarpal joint of thumb, basal osteotomy of first metacarpal in treatment of 854
— rheumatoid, tetraplegia in, with complete recovery after 327

CONTENTS OF VOLUME 60

Number 1

Original Papers PAGE

A Review of 460 Patients admitted to the Intensive-therapy Unit of a General Hospital between 1965 and 1969 *F. D. Skidmore* 1
The Calcium Palmitate Gall-stone *A. G. A. Cowie, D. June Sutor, Susan E. Wooley, and C. G. Clark* 16
Abdominal Actinomycosis *M. Davies and N. C. Keddie* 18
Unabsorbable Suture Material—A Rare Cause of Recurrent Stones in the Common Bile-duct *D. B. Mackie, Stephen Haynes, and Roy E. May* 23
Open Skin-grafting in Developing Countries *Ezzat A. Gibrail* 25
Vein-graft By-pass in Axillary and Brachial Artery Occlusions causing Claudication *P. B. Wood* 29
The Influence of Electrical Stimulation of the Leg during Surgical Operations on the Subsequent Development of Deep-vein Thrombosis *L. R. Dejode, M. Khurshid, and W. W. Walther* 31
Carcinoma of the Ampulla of Vater and Duodenum *L. H. Blumgart and A. Kennedy* 33
Local Recurrence in Primary Osteosarcoma of the Femur *Peter Hill* 40
Subtotal Colectomy and Caecoproctostomy *C. U. Webster and R. R. S. Howard* 42
Pseudocyst of the Pancreas *Alan Simpson and V. K. Srivastava* 45
Intracranial Subdural Abscess *D. I. Anagnostopoulos and Peter Gortvai* 50
Renal Function and Hypertension in Primary Hyperparathyroidism *S. D. Chowdhury and J. G. Gray* 53
Splenosis *W. J. Mackie and D. F. Miller* 56
Isotope Venography *J. H. Highman, E. O'Sullivan, and E. Thomas* 58
Stercoral Perforation of the Sigmoid Colon *D. C. Carter and J. R. Kirkpatrick* 61
Observations on Acute Pancreatitis *W. J. Gillespie* 63
Fundoplication for Hiatus Hernia *R. H. Franklin, F. I. Iweze, and M. S. Owen-Smith* 65
Torsion of the Isolated Fallopian Tube *J. M. Monaghan* 70
Short Notes of Rare or Obscure Cases 72
Reviews and Notices of Books 81

Number 2

Original Papers

Carcinoma involving the Lower Alveolus *E. Stanley Lee and J. S. P. Wilson* 85
Bacterial Flora in the Duodenum of Patients after Biliary Fenestration *E. Thomas, A. Kerr Grant, M. Holford, D. Ringwood, A. W. Derrington, and J. R. Magarey* 107
Starch and Intraperitoneal Adhesion Formation *D. G. Jagelman and H. Ellis* 111
Experimental Investigation of the Use of Cyano-acrylate Adhesive to prevent Biliary Leakage in Percutaneous Transhepatic Cholangiography *A. Georgakakis* 115
Kocher's Perampullary Approach for Common Bile-duct Calculi *A. E. Carter* 117
Traumatic Rupture of the Ileum *J. P. Evans* 119
Intramuscular Myxomas *R. D. Rosin* 122
Embryonic Rhabdomyosarcoma of the Urogenital Tract *S. Ghazali* 124

PAGE
The Diagnosis and Prophylaxis of Pulmonary Complications of Surgical Operation *G. Laszlo, G. G. Archer, J. H. Darrell, J. M. Dawson, and C. M. Fletcher* 129
Malnutrition and Malabsorption in Crohn's Disease with Reference to the Effect of Surgery *N. H. Dyer and A. M. Dawson* 134
Partial Hepatectomy using a Carbon-dioxide Laser - *R. R. Hall, A. D. Beach, and D. W. Hill* 141
The Effect of Increased Oxygen in Acute Limb Ischaemia *C. G. Stalker, A. J. McEwan, and I. McA. Ledingham* 144
The Aetiology and Prevention of Pancreatitis following Biliary-tract Operations *M. R. B. Keighley and N. G. Graham* 149
Computer-assisted Statistical Analysis of Skeletal Scintigrams - - - - *C. S. B. Galasko* 152
Short Notes of Rare or Obscure Cases - - - - - - - - - - - 156
Reviews and Notices of Books - - - - - - - - - - - - 165

Number 3

Original Papers

Adenocarcinoma and Crohn's disease - *S. G. Darke, A. G. Parks, J. L. Grogono, and D. J. Pollock* 169
The Use of Immunized Pig Lymph-node Cells in the Treatment of Patients with Advanced Malignant Disease - - - - - - - - - - *M. O. Symes and A. G. Riddell* 176
The Effect of Innervation, Denervation, and Muscle Type on the Reunion of Skeletal Muscle *P. Webb* 180
The Arterial Complications of Polycythaemia Vera *A. P. Barabas, D. N. Offen, and E. A. Meinhard* 183
High Blood Viscosity: An Aetiological Factor in Venous Thrombosis *John A. Dormandy and Joy B. Edelman* 187
Mechanical Sutures in Surgery - - - - - *Felicien M. Steichen and Mark M. Ravitch* 191
The Effect of Antral Acidification on Acid Secretion stimulated by Pentagastrin *M. H. Wheeler, R. J. Prescott, and A. P. M. Forrest* 197
The Controlled Use of Vasodilator Drugs in the Management of Hypovolaemia complicated by Diminished Cardiac Function - - - - - *K. M. Pagliero, A. K. Yates, and D. G. Hill* 201
Further Progress with Reconstruction of the Exstrophied Bladder *D. Innes Williams and James E. Keeton* 203
An Analysis of 59 Cases of Tracheal Stenosis following Tracheostomy with Cuffed Tube and Assisted Ventilation, with Special Reference to Diagnosis and Treatment *M. J. Andrews and F. G. Pearson* 208
Acalculous Gall-bladder Disease - - - - - - - *A. Gunn, N. C. Keddie, and H. Fox* 213
The Influence of the Vagus Nerves on the Biliary System - - - - - *D. S. Hopton* 216
Coeliac and Hepatic Nerve Function following Selective Vagotomy *S. T. D. McKelvey, D. Toner, A. M. Connell, and T. L. Kennedy* 219
The Kirschner Operation—A Forgotten Procedure - - - - - - - *G. B. Ong* 221
Closed Liver Injury: An Assessment of Prognostic Factors - *I. B. Faris and H. A. F. Dudley* 227
The Coagulum Pyelolithotomy - - - - - - - - - - - - *V. J. Patel* 230
'Fruit-stone Ileus' - - - - - - - - - *Paul C. Weaver and David H. Trapnell* 237
Short Notes of Rare or Obscure Cases - - - - - - - - - - - 240
Reviews and Notices of Books - - - - - - - - - - - - 250

Number 4

Original Papers

The Effects of Early Experimental Cryptorchidism and Subsequent Orchidopexy on the Maturation of the Guinea-pig Testicle - - - - - - - - - - - *P. M. Atkinson* 253
The Effect of Unilateral Experimental Cryptorchidism and Subsequent Orchidopexy upon Maturation of the Contralateral Scrotal Testicle of the Guinea-pig - - - - *P. M. Atkinson* 258
Sincipital Encephalomeningoceles - - - - - - - - - - *William J. Whatmore* 261
Hereditary Sacral Agenesis associated with Presacral Tumours - - - - *John S. Kenefick* 271
The Management of Upper Gastro-intestinal Tract Haemorrhage *M. M. Hegarty, R. T. Grime, and Philip F. Schofield* 275
Gastroduodenal Ulceration and Haemorrhage of Neurogenic Origin - - *Elizabeth A. Lewis* 279

PAGE
Carcinoma of the Prostate - - - - - - - *D. A. Aubrey and W. B. Peeling* 283
Intrapelvic Dermoid Cysts in Adolescent Girls presenting with Urinary Retention *C. J. L. Strachan* 287
Ruptured Spleen: A Radiological Pitfall and a Suggested Modification - *Peter G. A. Leigh* 289
Gastroduodenoscopy using an Irrigating Cystoscope - - - - - - *R. M. Kirk* 292
Regeneration of Parietal and Visceral Peritoneum - - - - - - *A. T. Raftery* 293
Maximal Gastric Secretion in Patients with Chronic Airway Obstruction *M. A. Hassan and M. Hobsley* 300
The Association of Peptic Ulcer and Abdominal Aortic Aneurysm and its Significance *J. Bouhoutsos, A. Barabas, and Peter Martin* 302

NUMBER 9

Original Papers

PAGE
Seat-belt Injuries of the Left Colon - *John Shennan* 673
Reversed Autogenous Saphenous Vein By-pass from the Common to the Deep Femoral (Profunda Femoris) Artery - *R. Berguer and L. T. Cotton* 676
Closed Injury of the External Iliac and Common Femoral Arteries *M. P. Brady, T. V. Keaveny, and P. A. Fitzgerald* 679
The Prevention of Postoperative Deep Venous Thrombosis with Dextran 70 *A. E. Carter and R. Eban* 681
Carcinoid Tumours of the Colon - *J. E. Scott* 684
A Sterile 'Use-once' Clip Applicator for Skin Closure - *David Annis* 686
The Management of Villous Tumours of the Large Bowel - *A. G. Parks and A. E. Stuart* 688
Management of Uncomplicated Diverticular Disease by Colonic Resection in Patients at St. Mark's Hospital, 1964–9 - *J. C. B. Penfold* 695
An Evaluation of the Fluorescein Test and Phlebography in the Detection of Incompetent Perforating Veins - *K. G. Callum, L. J. Gray, and M. Lea Thomas* 699
Gastric Secretory Response to Insulin Infusion in Vagotomized Subjects *D. C. Carter, R. R. Dozois, and J. R. Kirkpatrick* 702
A New Method for detecting Clotting in Shunts used for Haemodialysis *J. R. Salaman, J. Chu, and D. L. Crosby* 705
The Use of Gastrografin in the Relief of Residual and Late Bowel Obstruction in Cystic Fibrosis *J. F. McPartlin, J. A. S. Dickson, and V. A. J. Swain* 707
Peroperative Cholangiography - *Myat Thu Ya, D. Robinson, and A. A. Gunn* 711
Vagotomy and Pyloroplasty in the Elective Treatment of Gastric Ulcer *W. R. Lawson and J. S. F. Hutchison* 713
The Gastro-oesophageal Junction before and after Operations for Duodenal Ulcer *P. A. Thomas and R. J. Earlam* 717
Mucous Extravasation Theory as a Cause of Plunging Ranulas *W. E. W. Roediger, P. Lloyd, and H. H. Lawson* 720
An Investigation into the Spread of Bacterial Infection in Lower-limb Amputations *P. C. Weaver, B. Chattopadhyay, and J. Angel* 723
A Method of Supportive Bandaging for Amputation Stumps *P. C. Puddifoot, P. C. Weaver, and S. A. Marshall* 729
A Functional and Social Review of Lower-limb Amputees - *P. C. Weaver and S. A. Marshall* 732
Infarction of Fibro-adenoma of the Breast - *Joseph Newman and Leonard B. Kahn* 738
The Technique and Possible Application of Supra-orbital Artery Blood-pressure Estimation *A. P. Wyatt, K. Ratnavel, and G. E. Loxton* 741
Treatment of Combined External Iliac Artery and Vein Injury by Cross-over Femorofemoral Arterial and Venous Grafts with Temporary Arteriovenous Shunt - *A. M. N. Gardner* 744
Phytohaemagglutinin-stimulated Transformation of Peripheral and Lymph-node Lymphocytes in Patients with Gastro-intestinal Cancer - *P. J. Guillou, T. G. Brennan, and G. R. Giles* 745
Short Notes of Rare or Obscure Cases - 749
Reviews and Notices of Books - 754

NUMBER 10

Association of Surgeons of Great Britain and Ireland

Symposium on Modern Trends in the Management of Thyrotoxicosis

Opening Address - *W. Michie* 757
Radioactive Iodine Therapy for Thyrotoxicosis - *William R. Greig* 758
The Surgical Management of Thyrotoxicosis *C. A. S. Pegg, D. J. Stewart, P. D. Bewsher, and W. Michie* 765
Lymphoid Tissue in the Thyroid Gland and Thymus of Patients with Primary Thyrotoxicosis *J. Swanson Beck, R. J. Young, J. G. Simpson, Elizabeth S. Gray, A. G. Nicol, C. A. S. Pegg, and W. Michie* 769
Long-term Aftercare for Patients treated for Thyrotoxicosis - *Anthony J. Hedley* 771

Short Papers

Observations on the Treatment of Traumatic Urethral Injuries and the Value of the Fenestrated Urethral Catheter - *Richard Turner-Warwick* 775

PAGE

THE OUTCOME OF TREATMENT AND CHANGES IN PRESENTATION OF PRIMARY HYPERPARATHYROIDISM *D. C. Britton, I. D. A. Johnston, M. H. Thompson, and L. B. Fleming* 782

THE CONTINENT ILEOSTOMY - - - - - - - - - - - - - - *A. Cameron* 785

HIGHLY SELECTIVE VAGOTOMY WITHOUT A DRAINAGE PROCEDURE IN THE TREATMENT OF HAEMORRHAGE, PERFORATION, AND PYLORIC STENOSIS DUE TO PEPTIC ULCER *D. Johnston, P. J. Lyndon, R. B. Smith, and C. S. Humphrey* 790

A REVIEW OF 15 YEARS' EXPERIENCE IN THE USE OF SCLEROTHERAPY IN THE CONTROL OF ACUTE HAEMORRHAGE FROM OESOPHAGEAL VARICES - - - - - *George W. Johnston and Harold W. Rodgers* 797

Short Papers for the Moynihan Prize and Medal

URINARY HYDROXYPROLINE EXCRETION IN EARLY AND ADVANCED BREAST CANCER—A SEQUENTIAL STUDY *A. Cuschieri* 800

CARDIAC SEQUELAE OF HAEMORRHAGIC SHOCK - - - - - *C. S. McArdle and W. D. Fisher* 803

EARLY CHANGES IN THE POST-PHLEBITIC LIMB: THEIR CLINICAL SIGNIFICANCE *T. P. Corrigan and V. V. Kakkar* 808

THE INTESTINAL COMPLICATIONS OF RADIOTHERAPY - - - - *J. M. Wellwood and B. T. Jackson* 814

THE AETIOLOGY OF HYPERTENSION AFTER RENAL TRANSPLANTATION IN MAN *D. Sampson, R. Y. Kirdani, A. A. Sandberg, and G. P. Murphy* 819

THE ROLE OF CELLULAR IMMUNITY IN CONTROL OF NEOPLASIA - - - - *G. Bone and R. Camplejohn* 824

INHIBITION OF HUMAN GASTRIC SECRETION BY PROSTAGLANDIN *D. C. Carter, S. M. M. Karim, D. Bhana, and P. A. Ganesan* 828

PROPHYLAXIS IN ILIOFEMORAL VENOUS THROMBOSIS - *D. R. Harper, D. P. Dhall, and P. W. H. Woodruff* 831

A REPORT OF THE SYMPOSIUM ON GENERAL SURGICAL TRAINING - - - - *M. R. Williams* 832

Short Notes of Rare or Obscure Cases - - - - - - - - - - - - 834

Reviews and Notices of Books - - - - - - - - - - - - - 837

NUMBER 11

Original Papers

JAMES SHERREN—SURGEON AND SAILOR - - - - - - - - - *A. M. A. Moore* 841

PHYTOBEZOAR AFTER VAGOTOMY WITH DRAINAGE OR RESECTION - - - - *A. M. Mir and M. A. Mir* 846

A NEW VENOUS THROMBECTOMY TECHNIQUE - - - - - - - - - - *P. E. Kiely* 850

EXTENSIVE CERVICAL LAMINECTOMY - - - - - - - - - - *D. H. R. Jenkins* 852

BASAL OSTEOTOMY OF THE FIRST METACARPAL IN THE TREATMENT OF ARTHRITIS OF THE CARPOMETACARPAL JOINT OF THE THUMB - - - - - - - - - - - *J. N. Wilson* 854

SUBCAPITAL FRACTURES OF THE NECK OF THE FEMUR TREATED BY DOUBLE-DIVERGENT FIXATION *W. M. McQuillan, P. J. Abernethy, and J. Guy* 859

CARCINOMA OF THE DUODENUM: COMPARISON OF SURGERY, RADIOTHERAPY, AND CHEMOTHERAPY *Samuel Sakkar and C. C. Ware* 867

CIGARETTE CONSUMPTION AND ATHEROSCLEROSIS - - - - - - - - *G. Lawton* 873

THE 'ICED-GLOVE' METHOD OF TREATMENT OF PARAPHIMOSIS - - - - - *G. R. Houghton* 876

LUMBAR SYMPATHECTOMY - - - - - - - - - - - *J. C. Postlethwaite* 878

EFFECT OF CORPORAL AND ANTRAL GASTROJEJUNOSTOMY ON CANINE GASTRIC EMPTYING OF SOLID SPHERES AND LIQUIDS - - - - - - *Keith A. Kelly, Kenneth D. Morley, and Bruce G. Wilbur* 880

RUPTURED NON-TRAUMATIC ANEURYSMS OF THE DESCENDING THORACIC AORTA *T. G. J. Brightmore and C. E. Drew* 885

ABO BLOOD GROUPS IN OCCLUSIVE AND ECTATIC ARTERIAL DISEASE - *Tom Morris and John Bouhoutsos* 892

A REVIEW OF 174 PATIENTS WITH ARTERIAL EMBOLISM - - *W. A. L. MacGowan and R. Mooneeram* 894

SURGICAL RESEARCH SOCIETY - - - - - - - - - - - - - - 899

Clotmover

Kabikinase

(pure streptokinase for intravascular infusion)

For clots following surgery or long bed-stay

Thrombolytic therapy for

Clots in the legs

Clots in the lungs

Clots in the arteries

Kabikinase is manufactured by AB Kabi, Stockholm, Sweden and is available only from:

KABI

Kabi Pharmaceuticals Limited,
Bilton House, Uxbridge Road,
Ealing, London, W5 2TH.
Telephone: 01-567 4717 or 01-579 18[illegible]1

A handbook of information about thrombolytic therapy with Kabikinase will be sent on request.

Kabikinase is a registered trade mark.

PRINTED IN GREAT BRITAIN BY JOHN WRIGHT AND SONS LTD. AT THE STONEBRIDGE PRESS, BRISTOL BS4 5NU
